To my best friend and beautiful wife, Andrea, for her unconditional love and inspiration to pursue my dreams. To my daughters Katie, Kristyn, Chelsea, Morgan, and Kara, who are my never-ending sources of love, laughter, and adventure and remind me why life is so precious. I love you all! In memory of my father, Paul, who was a continuous source of encouragement and the epitome of perseverance. I have come to realize that he is my hero.

To Bill Brown, my EMS instructor, mentor, colleague, and most importantly my friend, an exemplary EMS educator, professional, and visionary, who instilled in me the meaning of commitment and a belief in excellence in emergency medical services.

To Lieutenant James Woodward and Specialist Joseph Buday (veteran of Operation Iraqi Freedom), who are currently serving in the U.S. Army; Vietnam combat veterans Raymond Courtney, William E. Brown, Jr., and James D. Lange; and all current military personnel and veterans, but especially combat veterans of foreign wars and conflicts who unselfishly served their country with duty and honor.

JJM

To my eternal sweetheart Diane, for her continual inspiration and support. Any success that I have enjoyed has been fueled by our relationship.

To the greatest children a father could be blessed with: Michael Scott, Holli, James, Brady, and Mandy, who grew up with EMS activity.

Lastly, to the new generation who are being EMS-educated in preparation for service to their communities across this great land—specifically my grandchildren Joshua Keith, Kennedi, Jackson David, Madilyn, Shelby, Little Scott, and the two new babies who will soon bless our family.

KJK

Dr. Brent Hafen was a man of great conviction. He was dedicated to his church, his family, his values, his students, and to the field of EMS. Previous editions of this text and others coauthored by Dr. Hafen have had a tremendous influence on EMS training and education. He is deeply missed as a colleague and friend.

KJK and JJM
### Brief Contents

#### PART 1
**Preparatory/Public Health**  
1 Emergency Medical Care Systems, Research, and Public Health  
2 Workforce Safety and Wellness of the EMT  
3 Medical, Legal, and Ethical Issues  
4 Documentation  
5 Communication  
6 Lifting and Moving Patients

#### PART 2
**Anatomy and Physiology/Medical Terminology**  
7 Anatomy, Physiology, and Medical Terminology

#### PART 3
**Pathophysiology**  
8 Pathophysiology

#### PART 4
**Life Span Development**  
9 Life Span Development

#### PART 5
**Airway Management, Respiration, and Artificial Ventilation**  
10 Airway Management, Artificial Ventilation, and Oxygenation

#### PART 6
**Assessment**  
11 Baseline Vital Signs, Monitoring Devices, and History Taking

### Detailed Contents

**Key Features** xix  
**EMT Skills** xxi  
**Preface** xxiii  
**What’s New in the 10th Edition?** xxv  
**About the Authors** xxxi

#### PART 1  
**Preparatory/Public Health** 1

1. **Emergency Medical Care Systems, Research, and Public Health** 1
   - **Introduction** 2  
   - **The Emergency Medical Services System** 2  
     - A Brief History 2  
     - Technical Assistance Program Assessment Standards 3  
   - **The EMT** 6  
     - Roles and Responsibilities 6  
     - Professional Attributes 9  
     - State EMS Agency Role 10  
     - Medical Direction/Medical Oversight 11  
     - Quality Improvement 11  
     - Issues in Patient Safety 12  
   - **Research and EMS Care** 12  
   - **Public Health** 13

2. **Workforce Safety and Wellness of the EMT** 17
   - **Introduction** 18  
   - **Emotional Aspects of Emergency Care** 18  
     - Death and Dying 18  
     - High-Stress Situations 20  
     - Stress Reactions 20  
     - Stress Management 21  
     - Critical Incident Stress Management 23  
   - **Scene Safety** 23  
     - Protecting Yourself from Disease 23  
     - Infectious Diseases of Concern to the EMT 28  
     - Protecting Yourself from Accidental and Work-Related Injury 31  
   - **Wellness Principles** 34  
     - Physical Well-Being 34  
     - Mental Well-Being 35

3. **Medical, Legal, and Ethical Issues** 39
   - **Introduction** 40  
   - **The Scope of Practice** 40  
     - Legal Duties 40  
     - Ethical Responsibilities 42  
   - **Issues of Patient Consent and Refusal** 43  
     - Types of Consent 43  
     - Advance Directives 43  
     - Refusing Treatment 44  
   - **Other Legal Aspects of Emergency Care** 48  
     - Negligence 48  
     - Intentional Tort 48  
     - Confidentiality 49  
     - Health Insurance Portability and Accountability Act (HIPAA) 50  
     - COBRA and EMTALA 50  
     - Protecting Yourself in Transport and Transfer Situations 50  
     - Special Situations 51

4. **Documentation** 56
   - **Introduction** 57  
   - **Functions of the Prehospital Care Report** 57  
     - Continuity of Medical Care 57  
     - Administrative Uses 57  
     - Legal Document 58  
     - Educational and Research Uses 58  
     - Evaluation and Continuous Quality Improvement 58  
   - **Collection of Data in Prehospital Care Reports** 58  
     - PCR Formats 58  
     - PCR Data 59  
   - **Legal Concerns** 66  
     - Confidentiality 66  
     - Distribution 66  
     - Refusal of Treatment 66  
     - Falsification 67  
   - **Special Situations** 68  
     - Transfer-of-Care Report 68  
     - Multiple-Casualty Incidents 68  
     - Special Reports 68  
   - **Alternative Documentation Methods** 68  
     - Soap 68  
     - CHART 69
Patient Positioning 107
Packaging Patients for Air Transport 108

General Guidelines for Carrying a Patient Using a Backboard, Portable Stretcher, or Flexible Stretcher 108
Two-Person Carry 109
Four-Person Carry 109
Carrying a Supine Patient on Stairs 109
Neonatal Isolette 109

PART 2
Anatomy and Physiology/Medical Terminology 118

7 Anatomy, Physiology, and Medical Terminology 118

Introduction 120
Anatomical Terms 120

Body Systems 122
The Musculoskeletal System 122
The Respiratory System 132
The Circulatory System 138
The Nervous System 144
The Endocrine System 148
The Integumentary System (Skin) 150
The Digestive System 150
The Urinary or Renal System 152
The Reproductive System 152

Medical Terminology 152
Medical Words and Word Parts 156

PART 3
Pathophysiology 164

8 Pathophysiology 164

Introduction 165
Cellular Metabolism 165
Aerobic Metabolism 165
Anaerobic Metabolism 166

Components Necessary for Adequate Perfusion 167
Composition of Ambient Air 168
Patency of the Airway 169
Respiratory Compromise Associated with Mechanics of Ventilation 170
Regulation of Ventilation 174
Ventilation/Perfusion Ratio 176
PART 4
Life Span Development 190

9 Life Span Development 190

Introduction 191
Life Span Development 191
    Neonates and Infants 191
    Toddlers and Preschool-Age Children 194
    School-Age Children 195
    Adolescence 196
    Early Adulthood 197
    Middle Adulthood 197
    Late Adulthood 198

PART 5
Airway Management, Respiration, and Artificial Ventilation 202

10 Airway Management, Artificial Ventilation, and Oxygenation 202

Introduction 204
Respiration 204
Respiratory System Review 204
    Anatomy of the Respiratory System 205
    Mechanics of Ventilation (Pulmonary Ventilation) Review 207
    Respiratory Physiology Review 209
    Pathophysiology of Pulmonary Ventilation and External and Internal Respiration 211
    Airway Anatomy in Infants and Children 212
Airway Assessment 213
    Airway Functions and Considerations 213
    Abnormal Upper Airway Sounds 214
    Opening the Mouth 215
    Opening the Airway 215
    Suctioning 218
    Airway Adjuncts 220
Assessment of Breathing 223
    Relationship of Tidal Volume and Respiratory Rate in Assessment of Breathing 223

Assessing for Adequate Breathing 224
    Adequate Breathing 225
    Inadequate Breathing 226

Making the Decision to Assist Ventilation or Not 228

Techniques of Artificial Ventilation 229
    Differences Between Normal Spontaneous Ventilation and Positive Pressure Ventilation 229
    Basic Considerations 230
    Mouth-to-Mouth Ventilation 232
    Mouth-to-Mask and Bag-Valve Ventilation: General Considerations 232
    Mouth-to-Mask Ventilation 234
    Bag-Valve-Mask Ventilation 236
    Flow-Restricted, Oxygen-Powered Ventilation Device (FROPVD) 239
    Automatic Transport Ventilator (ATV) 241
    Ventilation of the Patient Who Is Breathing Spontaneously 242
    Continuous Positive Airway Pressure (CPAP) 242
    Hazards of Overventilation 245

Special Considerations in Airway Management and Ventilation 246
    A Patient with a Stoma or Tracheostomy Tube 246
    Infants and Children 247
    Patients with Facial Injuries 248
    Foreign Body Airway Obstruction 248
    Dental Appliances 248

Oxygen Therapy 248
    Oxygen Cylinders 248
    Safety Precautions 249
    Pressure Regulators 249
    Oxygen Humidifiers 250
    Indications for Oxygen Use 250
    Hazards of Oxygen Administration 251
    Clinical Decision Making Regarding Oxygen Administration 251
    When and When Not to Administer Oxygen 252
    Oxygen Administration Procedures 252
    Terminating Oxygen Therapy 253
    Transferring the Oxygen Source: Portable to On-Board 253
    Oxygen Delivery Equipment 253

PART 6
Assessment 264

11 Baseline Vital Signs, Monitoring Devices, and History Taking 266

Introduction 267
Gathering Patient Information 267
### Medication Forms 401

#### Essential Medication Information 403
- Indications 403
- Contraindications 403
- Dose 403
- Administration 404
- Actions 404
- Side Effects 404

#### Key Steps in Administering Medications 404
- Obtain an Order from Medical Direction 404
- Select the Proper Medication 404
- Verify the Patient’s Prescription 405
- Check the Expiration Date 405
- Check for Discoloration or Impurities 405
- Verify the Form, Route, and Dose 405
- Medication Administration: The Five “Rights” 405
- Documentation 406

#### Reassessment Following Administration 406

#### Sources of Medication Information 406

### PART 8

#### Shock and Resuscitation 409

### 15 Shock and Resuscitation 409

#### Introduction 410

#### Shock 410
- Etiologies of Shock 411
- Categories of Shock 413
- Specific Types of Shock 417
- The Body’s Response to Shock 418
- Stages of Shock 419
- Shock Assessment 421
- Age Considerations in Shock 424
- General Goals of Prehospital Management of Shock 424

#### Resuscitation in Cardiac Arrest 424
- Pathophysiology of Cardiac Arrest 425
- Terms Related to Resuscitation 425
- Withholding a Resuscitation Attempt 426
- The Chain of Survival 426

#### Automated External Defibrillation and Cardiopulmonary Resuscitation 427
- Types of Defibrillators 427
- Analysis of Cardiac Rhythms 428
- When and When Not to Use the AED 430

#### Recognizing and Treating Cardiac Arrest 431
- Assessment-Based Approach: Cardiac Arrest 431
- Performing Defibrillation 432
- Transporting the Cardiac Arrest Patient 434
Detailed Contents

Checking the Blood Glucose Level 566
Diabetes Mellitus (DM) 566

Acute Diabetic Emergencies 568
Hypoglycemia 568
Oral Glucose 570
Hyperglycemia 570
Hyperglycemic Condition: Diabetic Ketoacidosis (DKA) 572
Hyperglycemic Condition: Hyperglycemic Hyperosmolar Nonketotic Syndrome (HHNS) 575

Assessment-Based Approach: Altered Mental Status in a Diabetic Emergency 577
Scene Size-up and Primary Assessment 577
History and Secondary Assessment 578
Emergency Medical Care 578
Reassessment 579
Summary: Assessment and Care 579

21 Anaphylactic Reactions 585

Introduction 586
Anaphylactic Reaction 586
Pathophysiology of Anaphylactic Reaction 586
Assessment-Based Approach to Anaphylactic Reaction 589
Summary: Assessment and Care 594
Epinephrine Auto-Injector 596

22 Toxicologic Emergencies 605

Introduction 606
Poisons and Poisonings 606
Poisons and Routes of Exposure 606
Managing the Poisoning Patient 608
Antidotes 608
Ingested Poisons 608
Assessment-Based Approach: Ingested Poisons 608
Activated Charcoal 611
Inhaled Poisons 613
Assessment-Based Approach: Inhaled Poisons 613
Injected Poisons 615
Assessment-Based Approach: Injected Poisons 615
Absorbed Poisons 616
Assessment-Based Approach: Absorbed Poisons 617
Summary: Assessment and Care 618
Specific Types of Poisoning 621
Food Poisoning 621
Carbon Monoxide Poisoning 621
Cyanide 622
Acids and Alkalis 623
Hydrocarbons 623
Methanol (Wood Alcohol) 624
Isopropanol (Isopropyl Alcohol) 625
Ethylene Glycol 625
Poisonous Plants 626
Suicide Bags 626

Poison Control Centers 626
Drug and Alcohol Emergencies 627
Assessment-Based Approach: Drug and Alcohol Emergencies 627
Summary: Assessment and Care 632
Managing a Violent Drug or Alcohol Abuse Patient 634
Specific Substance Abuse Considerations 636
Drug Withdrawal 637
The Alcoholic Syndrome 637
The Withdrawal Syndrome 638
PCP, Cocaine, Amphetamines, Methamphetamines, and PABS 640
Medication Overdose 641
Huffing 641

23 Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies 647

Introduction 648
Acute Abdomen 648
Abdominal Structures and Functions 648
Abdominal Pain 650
Conditions That May Cause Acute Abdominal Pain 652
Assessment-Based Approach: Acute Abdomen 657
Summary: Assessment and Care 660
Hematologic Emergencies 660
The Nature of Hematologic Emergencies 660
Gynecologic Emergencies 663
Female Reproductive Structures and Functions 663
Gynecologic Conditions 663
Assessment-Based Approach: Gynecologic Emergencies 667
Genitourinary/Renal Emergencies 668
Genitourinary/Renal Structures and Functions 668
Genitourinary/Renal Conditions 669
Assessment-Based Approach: Genitourinary/Renal Emergencies 672

24 Environmental Emergencies 676

Introduction 677
Heat and Cold Emergencies 677
Regulation of Temperature 677
Exposure to Cold 680
Generalized Hypothermia 680
Pathophysiology of Generalized Hypothermia 681
30 Musculoskeletal Trauma and Nontraumatic Fractures 832

Introduction 833
Musculoskeletal System Review 833
The Muscles 833
Tendons and Ligaments 833
Cartilage 834
The Skeletal System 834
Injuries to Bones and Joints 836
Types of Injuries 836
Mechanism of Injury 838
Critical Fractures: The Femur and the Pelvis 839
Assessment-Based Approach: Bone or Joint Injuries 839
Summary: Assessment and Care 842

Basics of Splinting 842
General Rules of Splinting 843
Splinting Equipment 846
Hazards of Improper Splinting 847
Splinting Long Bone Injuries 847
Splinting Joint Injuries 848
Traction Splinting 848
Splinting Specific Injuries 848
Pelvic Fracture 848
Compartment Syndrome 849

Nontraumatic Fractures 849

31 Head Trauma 862

Introduction 863
Anatomy of the Skull and Brain 863
The Skull 863
The Brain 863
Head Injury 865
Scalp Injuries 865
Skull Injuries 865
Brain Injuries 865
Pathophysiology of Traumatic Brain Injury 865
Assessment-Based Approach: Head Injury 869
Summary: Assessment and Care 876

32 Spinal Column and Spinal Cord Trauma 881

Introduction 882
Anatomy and Physiology of Spine Injury 882
The Nervous System 882
The Skeletal System 882
Common Mechanisms of Spine Injury 884
Spinal Column Injury Versus Spinal Cord Injury 886
Emergency Care for Suspected Spine Injury 888
Assessment-Based Approach: Spine Injury 888
Summary: Assessment and Care 894

Assessing and Providing Emergency Care to Combat Veterans: Recommendations for EMTs 1151

PART 12
EMS Operations 1155

42 Ambulance Operations and Air Medical Response 1155

Introduction 1156
Driving the Ambulance 1156
- Laws, Regulations, and Ordinances 1156
- Driving Excellence 1156
Warning Devices 1160
- Colors and Markings 1160
- Warning Lights and Emergency Lights 1160
- Using Your Siren 1161
- Using Your Air Horn 1161
Roadway Incident Scene Safety 1161
- High-Visibility Apparel 1161
- Safety Benchmarks 1162
Phases of an Ambulance Call 1162
- Daily Prerun Preparation 1163
- Dispatch 1164
- En Route to the Scene 1164
- At the Scene 1164
- En Route to the Receiving Facility 1167
- At the Receiving Facility 1167
- En Route to the Station or Response Area 1168
- Post Run 1168
Air Medical Transport 1169
- When to Request Air Medical Transport 1169
- Requesting Air Medical Transport 1170
- Additional Considerations for Air Medical Transport 1170
- Setting Up a Landing Zone 1170
Security and Safety 1171
- Operational Security Measures 1171
- Carbon Monoxide in Ambulances 1173

43 Gaining Access and Patient Extrication 1179

Introduction 1180
Planning Ahead 1180
- Dispatch 1180
- Location 1180
- Motor Vehicle Collisions 1180
Sizing up the Scene 1181
- Perform a 360-Degree Assessment 1181
- Evaluate the Need for Additional Resources 1181
- Personal Protective Equipment 1181
Key Features

Assessment Summaries

Cardiac Arrest 435
Respiratory Distress 479
Cardiac Compromise and Acute Coronary Syndromes 517
Stroke 540
Seizures 555
Acute Diabetic Emergency: Suspected Hypoglycemia 579
Anaphylactic Reaction 595
Poisoning Emergency 618
Drug or Alcohol Emergency 633
Acute Abdominal Pain 661
Cold Emergency 692
Heam Emergency 700
Drowning 722
Behavioral Emergency 742
Bleeding and Hemorrhagic Shock 784
Soft Tissue Trauma 798
Burn Emergency 825
Musculoskeletal Injury 843

Head Injury 876
Spine Injury 894
Chest Trauma 960
Abdominal Trauma 971
Antepartum (Preadelivery) Obstetric Emergency 999
Obstetric Emergency—Active Labor and Delivery 1012
Respiratory or Cardiopulmonary Emergency in the Pediatric Patient 1059

Emergency Care Protocols

Cardiac Arrest 435
Respiratory Distress 480
Cardiac Compromise and Acute Coronary Syndromes 518
Stroke 541
Seizures 556
Acute Diabetic Emergency 580
Anaphylactic Reaction 596
Poisoning Emergency 619
Drug or Alcohol Emergency 634
Acute Abdominal Pain 661
Generalized and Local Cold Emergencies 693
Heat Emergency 701
Drowning 723
Behavioral Emergency 743
Bleeding and Hemorrhagic Shock 785
Soft Tissue Trauma 799
Burn Emergency 826
Musculoskeletal Injury 844
Head Injury 877
Spine Injury 895
Eye Injury 932
Facial Injury 936
Neck Injury 937
Chest Trauma 961
Abdominal Trauma 972
Antepartum (Preadelivery) Obstetric Emergency 1000

Obstetric Emergency—Active Labor and Delivery 1013
Newborn Infant 1018
Pediatric Shock 1058
Respiratory or Cardiopulmonary Emergency in the Pediatric Patient 1060
Pediatric Seizures 1063
Pediatric Altered Mental Status 1064
Pediatric Drowning 1065
Pediatric Fever 1066
Pediatric Poisoning 1068
Sudden Infant Death Syndrome 1070
Pediatric Trauma 1077
Pediatric Abuse and Neglect 1078

Emergency Care Algorithms

Automated External Defibrillator 436
Respiratory Distress/Failure/Arrest 481
Cardiac Compromise 519
Stroke 542
Seizures 557
Acute Diabetic Emergency 581
Anaphylactic Reaction 597
Poisoning Emergency 620
Drug or Alcohol Emergency 635
Acute Abdominal Pain 662
Cold Emergency 694
Heam Emergency 702
Drowning Emergency 724
Behavioral Emergency 744
Bleeding and Shock 786
Open Soft Tissue Trauma 800
Burn Emergency 827
Musculoskeletal Injury 845
Head Injury 878
Spine Injury 896

Chest Trauma 962
Abdominal Trauma 973
Antepartum (Preadelivery) Obstetric Emergency 1001
Obstetric Emergency—Active Labor and Delivery 1014

Preface

Congratulations on your decision to undertake an EMT education program. The field of emergency medical services is extremely rewarding and will provide you with experiences you will find both challenging and gratifying.

Be Prepared

As an EMT student, you have a few pressing concerns. You want to be prepared:

• To pass your course exams
• To pass the credentialing exam that allows you to practice as an EMT
• To treat patients to the best of your ability
• To do well in all aspects of your job

As the authors, we want to assure you that Prehospital Emergency Care, 10th Edition, is written to help you achieve those goals.

It All Makes Sense

The key to the above goals—passing your exams, providing excellent patient care, and doing well in your job—is understanding how everything fits together:

• A basic understanding of anatomy, physiology, and pathophysiology will allow you to better understand signs, symptoms, and emergency care.
• An anatomical and body systems approach to the physical exam will link conditions to assessment findings.
• Knowledge of the presentations of common medical conditions and traumatic injuries encountered in the prehospital environment will enable you to perform efficient and accurate assessments.
• A diagnostic-based approach to patient assessment will allow you to form a differential field impression of the condition or injury.
• An assessment-based approach to patient assessment will allow you to identify and provide immediate emergency care for life-threatening conditions or injuries.
• You will learn how to provide the most efficient and effective emergency care.

The good news is that—although what you have to learn may seem daunting in the beginning—it all makes sense. In fact, that is the philosophy behind this textbook. Our purpose has been to show you at every step of your EMT education program how: It all makes sense!

Features

All of the features in this text book are designed to help you navigate through the anatomy, physiology, pathophysiology, assessment findings, medical conditions, traumatic injuries, and emergency care to best prepare you to provide excellent emergency medical services to the patient—beginning with the dispatch of the call, followed by assessment and management of the patient and delivery to the medical facility, through writing your prehospital care report. In addition to the 275 new photographs and 70 new illustrations, in the “clinical” chapters (on airway care, the medical chapters, and the trauma chapters) you will find:

• Assessment Tips
• Understanding Body Processes
• Drug Profiles
• Assessment Summaries
• Emergency Care Protocols
• Emergency Care Algorithms

And a special feature that appears throughout Chapter 13, “Patient Assessment”:

• Critical Findings, which explains, at every step of the assessment, critical conditions/signs/symptoms you may find . . . what might be causing them . . . and specifically what you should do when your assessment of the patient reveals one of these critical findings.

EMTs are often taught WHAT signs and symptoms they should expect to see in certain conditions and WHAT should be done; however, the WHY of assessment and emergency care is often not well addressed. Two of the features, “Pathophysiology Pearls” and “Assessment Tips”—in addition to expanded discussion within the chapters—provide you with a basic understanding so that you can better comprehend WHY you are seeing signs and symptoms and WHY you are providing specific emergency care.

The Assessment Summaries, Emergency Care Protocols, Emergency Care Algorithms, and Critical Thinking features provide the most up-to-date strategies for providing competent care. These features and the entire text have been updated to conform to the latest American Heart Association guidelines.

In Your EMS Career

In your EMS career, you will respond to a variety of calls in uncontrolled environments requiring confidence,
compassion, and a high degree of competence. As an EMT, you will be put to the test to think critically and respond instantaneously. The foundation for these skills will be provided in your education program; you will learn further and gain better clinical insight through patient contact, continuing education, and experience. Once you have read this text book and complete your EMT program, you will have only begun your educational experience as an EMT. Every day you should strive to learn something new that may enhance your emergency patient care. Due to the dynamic nature of emergency medical services, you will become a lifelong learner.

**Pathophysiology**

As an EMT, you will be required to learn about many patient conditions and injuries that you will encounter in the prehospital environment. Identifying these conditions and injuries is most often based on the recognition of specific signs and symptoms and history findings. Not only is it difficult to memorize the myriad of signs and symptoms for each condition or injury, it is not desirable because not every patient presents with just one condition or injury or all of the same signs and symptoms. A good basic foundation of pathophysiology helps you to understand and explain the “why” behind the patient presentation. There is no need to memorize when you understand and can explain why each sign or symptom is occurring. Putting this together with a fundamental understanding of the pathophysiology of the conditions and a thorough approach to patient assessment will allow you to quickly recognize immediate life threats and provide excellent emergency care. Don’t memorize, but understand. This is the foundation to making “it all make sense!”

**The Importance of Patient Assessment**

Patient assessment is one of the most important skills that an EMT performs, requiring good practical ability and also the capability to think critically. You must take each finding from the assessment, determine if an immediate lifesaving intervention is required, store the information learned in the back of your mind as you continue with the assessment, and finally put all the pieces of the assessment together to provide effective emergency medical care. The challenge is similar to putting a puzzle together. You start out with individual pieces of the puzzle that have to be connected together to form a meaningful picture. The pieces of the puzzle correlate to signs, symptoms, and other findings of the assessment. You must take the findings, consider them individually, and then put them together to form a whole picture of your patient. Specific findings are meaningless without fitting them into the entire picture.

**Using Medical Terminology**

As you progress through your education program, you will learn a new system of communication that involves the use of appropriate medical terminology. It is important to establish a basic understanding of medical terminology so that you may communicate effectively, by both written and oral means, with other members of the medical team. *Prehospital Emergency Care*, 10th Edition, addresses medical terminology within Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and has integrated a basic foundation of medical terminology into each chapter (see the terms in bold type and the glossary at the end of the book) that will help you to enhance your professional image and communication skills. You should expand your medical terminology base as you continue your education.

**As You Begin Your EMS Career**

We wish you the best of luck as you begin your career in emergency medical services. Our best piece of advice to you is to provide the best emergency care possible and always do what is right for the patient. This will allow you to contribute to the mission of emergency medical services.

Good luck and best wishes!

*Joseph J. Mistovich and Keith J. Karren*
Prehospital Emergency Care, 10th Edition, continues to meet the National EMS Education Standards published by the National Highway Traffic Safety Administration in 2009 and to reflect the latest and best medical knowledge and practices in emergency medical services in the United States. Recognizing, as well, that equipment, standards, and practices vary from one state and local EMS service to another, the statement “follow local protocols” appears in numerous places throughout the text.

The content of Prehospital Emergency Care, 10th Edition, is summarized here, with emphasis on “what’s new” in this edition. The text’s table of contents is organized to follow the National EMS Educational Standards.

Preparatory; Public Health

The chapters that fall under the first two standards, “Preparatory” and “Public Health,” set the foundation for the chapters that follow with such basic topics as EMS systems; research; public health; workforce safety and wellness; medical, legal, and ethical issues; documentation; communication; and lifting and moving patients.

What’s New?

• Chapter 1, “Emergency Medical Care Systems, Research, and Public Health,” includes updated information on cell phone access to 911 as well as updated information on Voice over Internet Protocol (VoIP) access to 911. A section on State EMS agency roles and responsibilities has been added.

• Chapter 2, “Workforce Safety and Wellness of the EMT,” includes new information on diseases that are infectious but not communicable, such as malaria and severe acute respiratory distress syndrome (SARS) transmission, incubation, and protective measures.

• Chapter 3, “Medical, Legal, and Ethical Issues,” contains a new section on medical alert tattoos and a new section on baby safe haven laws regarding infant abandonment.

• Chapter 5, “Communication,” has a new section on advanced automatic collision notification (AACN) technology.

• Chapter 6, “Lifting and Moving Patients,” offers new information on power cots with mechanisms that reduce repetitive motion and back strain for EMTs.

Pathophysiology

This standard is covered in one chapter, “Pathophysiology.”

What’s New?

• Chapter 8, “Pathophysiology,” includes new information about respiratory centers in the brain and signs of hypoxia, along with a revised table of ventilation rates and an updated section on bag-valve ventilation. There are new sections on initiating and administering CPAP and a new section titled “Clinical Decision Making Regarding Oxygen Administration.”

Life Span Development

This standard is covered in one chapter, Chapter 9, “Life Span Development.” This chapter is unchanged from the prior edition.

Airway Management, Artificial Ventilation, and Oxygenation

This standard is covered in one chapter, “Airway Management, Artificial Ventilation, and Oxygenation.”

What’s New?

• Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation,” includes a new section explaining hypoxemia.

Assessment

The chapters that fall under the “Assessment” standard are those that detail baseline vital signs, monitoring devices, and history taking as well as scene size-up and the process of patient assessment.

What’s New?

• Chapter 13, “Patient Assessment,” includes an increased emphasis on assessing the patient’s oxygenation status, signs of inadequate oxygenation, and administration of oxygen.

Pharmacology

This standard is covered in one chapter, “Pharmacology Medication and Administration.”

What’s New?

• Chapter 14, “Pharmacology Medication and Administration,” as in Chapter 13, “Patient Assessment”—includes an increased emphasis on assessing the patient’s oxygenation status, signs of inadequate oxygenation, and administration of oxygen.

Anatomy and Physiology; Medical Terminology

These standards are covered in a single chapter, Chapter 7, “Anatomy, Physiology, and Medical Terminology.” This chapter is unchanged from the prior edition.
Shock and Resuscitation

What’s New?

- Chapter 15, “Shock and Resuscitation,” now includes information about the Pediatric Chain of Survival (along with the already-included adult Chain of Survival). A table concerning “Physical Assessment Indicators of Hypovolemic Shock” has been added.

What's New in the 10th Edition?

- Chapter 16, “Respiratory Emergencies,” has been extensively revised and updated. Included are an expanded (more nuanced) explanation of normal breathing. Additionally, hypoxemia is newly defined as an SpO2 reading of <94% (throughout the text as well as in Chapter 16). There is additional emphasis and detail regarding intervention when the patient complains of breathing difficulty. An expanded discussion of and distinction between emphysema and chronic bronchitis has been added. New tables have been inserted: “Signs of Improvement During the Administration of CPAP” and “Signs of Deterioration During the Administration of CPAP.” The chapter includes expanded discussion of the signs, symptoms, assessment, and care for asthma, pneumonia, pulmonary embolism, acute pulmonary edema, spontaneous pneumothorax, hyperventilation syndrome, and epiglottitis.

- Chapter 17, “Cardiovascular Emergencies,” presents, throughout the chapter, expanded discussion of guidelines for administration of supplemental oxygen according to the 2010 AHA guidelines. A new section is included: “The Dangers of Administering Too Much Oxygen in Acute Coronary Syndrome.”

- Chapter 18, “Altered Mental Status, Stroke, and Headache,”—similarly to Chapter 17 “Cardiovascular Emergencies”—includes expanded discussion of guidelines for administration of supplemental oxygen according to the 2010 AHA guidelines and a new section: “The Dangers of Administering Too Much Oxygen in Stroke.”

- Chapter 19, “Respiratory Emergencies,” has been extensively revised and updated. Included is a reconsideration of the relative importance of mechanism of injury in trauma assessment (now emphasizing MOI as the third consideration behind physiological and anatomical considerations.)

- Chapter 20, “Acute Diabetic Emergencies,” includes an expanded discussion of guidelines for administration of supplemental oxygen.

- Chapter 21, “Anaphylactic Reactions,” clarifies, throughout the chapter, the difference between IgE-mediated (anaphylactic) and non-IgE-mediated (anaphylactoid) reactions. Expanded information is included on causes, assessment, and management of anaphylactoid and anaphylactic reactions as well as information on distinguishing and caring for local versus systemic allergic reactions. Throughout the chapter, there is expanded discussion of guidelines for administering supplemental oxygen.

- Chapter 22, “Toxicologic Emergencies,” includes, throughout the chapter, expanded discussion of guidelines for administering supplemental oxygen. New sections are included on “Suicide Bags” (a method of committing suicide) and “Bath Salts” (an illegal psychoactive drug).

- Chapter 23, “Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies,” includes a new section, “Hematologic Emergencies,” that includes discussion of anemia, hemophilia, and sickle cell anemia/sickle cell crisis. Throughout the chapter, there is expanded discussion of guidelines for administering supplemental oxygen.

- Chapter 24, “Environmental Emergencies,” present a new table, “Stages of Hypothermia and Associated Physiological Changes.” Throughout the chapter, there is expanded discussion of guidelines for administering supplemental oxygen.

- Chapter 25, “Submersion Incidents: Drowning and Diving Emergencies,” includes, throughout the chapter, expanded discussion of guidelines for administering supplemental oxygen.

- Chapter 26, “Behavioral Emergencies,” has been extensively revised to include expanded definitions and discussion of behavior and psychiatric disorders, including these topics: mood, affect, “word salad,” tardive dyskinesia, anxiety, phobias, depression, bipolar disorder, paranoia, psychosis, and schizophrenia. There is also expanded discussion of assessment and care for violence, including attempted suicide and violence to others. The section “Dealing with Behavioral Emergencies” has been thoroughly revised and updated.

Trauma

What’s New?

- Chapter 27, “Trauma Overview: The Trauma Patient and the Trauma System,” includes a reconsideration of the relative importance of mechanism of injury in trauma assessment (now emphasizing MOI as the third consideration behind physiological and anatomical considerations.)

- Chapter 28, “Bleeding and Soft Tissue Trauma,” provides expanded discussion of guidelines for administration of supplemental oxygen throughout the chapter. (The discussion of hemophilia, formerly included in this chapter, has been moved to Chapter 23, as noted earlier.)
• Chapter 29, “Burns,” includes an increased emphasis on oxygenation in treatment of burns and toxic inhalations along with an expanded discussion of guidelines for administration of supplemental oxygen throughout the chapter.

• Chapter 30, “Musculoskeletal Trauma and Nontraumatic Fractures,” includes a new section on nontraumatic fractures (now included in the chapter title). Throughout the chapter, there is expanded discussion of guidelines for administering supplemental oxygen.

• Chapter 32, “Spinal Column and Spinal Cord Trauma,” includes a new section, “Indications for Spinal Immobilization Based on Assessment Findings.”

• Chapter 34, “Chest Trauma,” now warns that stabilization of a flail segment or placing the patient on the injured side may compromise chest wall motion and promote collapse of lung tissue. Newly emphasized is the recommendation of continuous positive air pressure (CPAP) with supplemental oxygen for flail segment. A new segment, “Commotio Cordis” has been added, and there is revised and updated information on treatment of pericardial tamponade.

• Chapter 35, “Abdominal and Genitourinary Trauma,” provides expanded discussion of guidelines for administration of supplemental oxygen throughout the chapter.

• Chapter 36, “Multisystem Trauma and Trauma in Special Patient Populations,” in the discussion of pediatric trauma assessment, now includes the American Heart Association Pediatric Advanced Life Support (PALS) assessment as an alternative to the American Academy of Pediatrics Pediatric Assessment Triangle (PAT), which is still included. Both assessment methods are now discussed.

What’s New?

• Chapter 37, “Obstetrics and Care of the Newborn,” now emphasizes oxygenation of the pregnant patient regardless of the SpO2 reading. Routine suctioning of the infant is no longer recommended (suction only if necessary). Current AHA guidelines for assessment and initial management of the newborn are now included.

• Chapter 38, “Pediatrics,” now includes the American Heart Association Pediatric Advanced Life Support (PALS) assessment as an alternative to the American Academy of Pediatrics Pediatric Assessment Triangle (PAT), which is still included. Both assessment methods are now discussed. A section on “Child Abuse” has been moved to this chapter (formerly in Chapter 40, “Patients with Special Challenges”).

• Chapter 39, “Geriatrics,” provides expanded discussion of guidelines for administration of supplemental oxygen throughout the chapter. A section on “Elder/Geriatric Abuse” has been moved to this chapter (formerly in Chapter 40, “Patients with Special Challenges”).

• Chapter 40, “Patients with Special Challenges,” no longer includes the sections on child abuse and elder abuse, which have now been moved to Chapters 38 and 39 on pediatrics and geriatrics, but continues to cover other special challenges.

• Chapter 41, “The Combat Veteran,” is a new chapter in this edition. Patients who are veterans of combat, whether they saw service recently or long ago, are likely to be suffering from the effects of post-traumatic stress disorder (PTSD) and possibly also from traumatic brain injury (TBI), which may be the cause of or an exacerbating factor in the present emergency. The chapter lists clues that may be present at the scene or in the patient’s demeanor or behavior that should alert the EMT to the patient’s status as a combat veteran. The chapter also presents advice about special considerations for assessment and treatment of this patient.

EMS Operations

The chapters within the “EMS Operations” standard are chapters on ambulance and air medical operations, gaining access and patient extrication, hazardous materials, multiple-casualty incidents and incident management, and EMS response to terrorism and weapons of mass destruction. There are no significant changes to these chapters from the prior edition.

We Want to Hear from You

Many of the best ideas for improving our text books and training for future EMTs comes from the instructors and students who use our books and ancillary materials. If you have ideas to offer us or questions to ask, you can reach us at the addresses listed below.

Contact Joseph Mistovich at:
jmistovich@ysu.edu

Visit the Brady website at:
www.bradybooks.com
We wish to thank the following groups of people for their assistance in developing the 10th Edition of *Prehospital Emergency Care*.

### Medical Editor

Our special thanks to Howard A. Werman, MD, FACEP, Professor, Department of Emergency Medicine, and Medical Director, MedFlight, The Ohio State University College of Medicine and Public Health, Columbus, Ohio. Dr. Werman reviewed the entire manuscript to ensure that the highest degree of medical accuracy was attained. His insight and expertise were invaluable to the development of the text.

### Contributing Writers

We would like to express special appreciation to the following specialists who contributed to chapter development in the 10th Edition.

Janet M. Gorsuch, RN, MS, CRNP
Nurse Practitioner
Akron Children’s Hospital Boardman, OH

Brandt S. Lange, BA, CEP/EMT-P
Engineer/Paramedic
Chandler Fire Department Chandler, Arizona

James D. Lange, PhD
Mesa, Arizona

Kristyn Mistovich, MSW, LSW
Acute Adolescent Therapist
Pomegranate Health Systems Columbus, OH

### Reviewers

The following reviewers of 10th Edition material provided invaluable feedback and suggestions.

Sandra (Sam) Bradley, BS, EMT-P
EMS QI and Training, freelance writer and photographer

East Contra Costa Fire Protection District
Pittsburg, CA

Michael Fisher, BHS, NREMT-P
Professor, Director of Human Patient Simulation
STAT Center-Simulation Technologies and Training
Greenville Technical College
Greenville, SC

Greg Friese, MS, NREMT-P
President, Emergency Preparedness Systems LLC

Photo Coordinators
Thanks to the following for valuable assistance coordinating models, props, and locations for our photo shoots:
Judy French, EMT-I, Alfred Rescue
Shelly McLaughlin, UNM Emergency Medical Services Academy
Kelly Roderick, KVEMSC
Brenda Schultz, Columbus Division of Fire

Photo Assistant and Digital Post-Production
Steve DeRoma, Albuquerque, NM
Joseph J. Mistovich, MEd, NREMT-P
Joseph Mistovich is Chairperson of the Department of Health Professions and a Professor at Youngstown State University in Youngstown, Ohio. He has more than 28 years of experience as an educator in emergency medical services.

Mr. Mistovich received his Master of Education degree in Community Health Education from Kent State University in 1988. He completed a Bachelor of Science in Applied Science degree with a major in Allied Health in 1985, and an Associate in Applied Science degree in Emergency Medical Technology in 1982 from Youngstown State University.

Mr. Mistovich is an author or coauthor of numerous EMS books and journal articles and is a frequent presenter at national and state EMS conferences.

Keith J. Karren, PhD, EMT-B
Keith J. Karren is Professor Emeritus and former Chair of the Department of Health Science at Brigham Young University in Provo, Utah. He has been a professional Health Science and EMS educator and author for 40 years. Dr. Karren received his Bachelor of Science and Master of Science degrees from Brigham Young University in 1969 and 1970 and his PhD in Health Science from Oregon State University in 1975. Dr. Karren was one of the earliest certified EMTs in Utah and helped found SAVERS, a community volunteer EMS ambulance association in Utah. Dr. Karren co-founded the Prehospital Emergency Care and Crisis Intervention Conference, held annually in Salt Lake City for 36 years, one of the premier EMS conferences in North America. Dr. Karren is the author or coauthor of numerous books on prehospital emergency care and health, including *First Aid for Colleges and Universities, First Responder: A Skills Approach*, and *Mind/Body Health*.

PREHOSPITAL EMERGENCY CARE

10th Edition

J O S E P H  J. M I S T O V I C H  •  K E I T H  J. K A R R E N
Medical Editor Howard A. Werman, MD
Standards and Competencies

Listed at the opening of each chapter is the Education Standard (or Standards) around which the chapter is written.

Also listed is the Competency (or Competencies) that identifies fundamental knowledge as well as patient assessment and management skills for the chapter.

Objectives

Objectives form the basis of each chapter and were developed around the Education Standards and Instructional Guidelines.

Key Terms

Page numbers identify where each key term first appears in the chapter.

Case Study and Follow-up

Each chapter opens with a case study relevant to the chapter topic. The case draws students into the subject and creates a link between the text and real-life situations and experiences.
Pathophysiology Pearls

This feature offers snapshots of pathology considerations students will encounter in the field. It highlights the body processes that lead to medical conditions found in patients. Understanding body processes aids in making the right treatment decisions for them.

Assessment Tips

These suggestions offer clinical insights into patient assessment that EMTs learn over time through experience.

They enable the EMT to more accurately conduct an assessment and interpret the findings.

Pathophysiology Pearls

Hyperglycemic patients have too much glucose in the blood and not enough insulin. The cells in the body are starving, even though the blood glucose level may be extremely high, because there is not enough insulin to move the glucose into the cells. At the same time, however, the brain is getting more than an adequate amount of glucose.
A Guide to Key Features

Photos and Drawn Art

Over one hundred new photos were shot for this edition of Prehospital Emergency Care. Many others were carefully researched from EMS and medical sources.

The photos work in combination with a unique, beautifully drawn art program to reinforce content coverage and add to text explanations.

Tables

A variety of tables highlight, summarize, and compare information.

Critical Findings

Critical Findings tables are unique to Chapter 13, Patient Assessment. They highlight types of trauma injuries, suggest possible findings, present injury possibilities based on this information, and summarize emergency care needed.

Critical (Unstable) Findings: The Posterior Body

Critical Finding: Open wound to the posterior thorax

Possibility: Sucking chest wound

Lung injury (pneumothorax)

Emergency Care: Occlude the open wound immediately with a gloved hand and then with a nongloved dressing or occlusive dressing taped on three sides. Rapid transport upon recognition. Consider ALS intervention. Establish an airway, begin positive pressure ventilation at 10–12mL/kg if respiratory rate or tidal volume is inadequate, and administer oxygen. Caution: Aggressive PPV may worsen a lung injury.

Critical Finding: Open wound with spurting or steadily flowing blood loss

Possibility: Lacerated artery or vein

Emergency Care: Apply direct pressure to the wound.

Apply pressure dressing if possible. Rapid transport. Administer oxygen.
Oral Glucose

**Medication Name**
Oral glucose is the generic name. Two of the trade names of oral glucose are:
- Glucose
- Insta-Glucose

**Indications**
Oral glucose should be administered to a patient who meets all three of the following criteria:
1. An altered mental status
2. A history of diabetes controlled by medication or a blood glucose level less than 60 mg/dL
3. The ability to swallow the medication

**Contraindications**
Oral glucose should not be administered to a patient who:
- Is either unresponsive or unable to swallow the medication
- Has a confirmed blood glucose level greater than 60 mg/dL

**Medication Form**
Gel, in toothpaste-type tubes.

**Dosage**
Oral glucose is a viscous gel typically packaged in toothpaste-type tubes. The typical dosage is one tube.

**Administration**
To administer oral glucose:
1. Obtain an order from medical direction. Off-line medication orders would allow the EMT to administer the oral glucose without direct consultation with medical direction. An on-line order may be given by direct consultation with medical direction via phone or radio prior to the administration of the medication.
2. Ensure the signs and symptoms are consistent with hypoglycemia. If protocol permits, obtain a blood glucose reading.
3. Ensure that the patient is responsive and able to swallow the medication and protect his airway. Monitor the patient’s airway closely during the administration to avoid accidental aspiration or aspiration of the oral glucose.
4. There are two ways to administer the medication. One way is to hold back the patient’s cheek and have him squeeze the glucose himself into his mouth. Another alternative method is to have the patient squeeze small portions of the contents of the tube into the mouth between the cheek and gum (Figure 20-4). An alternative method is to have the patient squeeze the glucose himself into his mouth. This ensures he is alert enough to swallow it.

**Actions**
Increases blood glucose levels. Increases glucose available to the brain.

**Side Effects**
There are no side effects of oral glucose when administered properly. However, the thickness of the gel may cause the patient to choke or aspirate the contents. Also, lightly massage the area between the cheek and gum to disperse the gel and increase absorption.

**Drug Profiles**
Drug summaries provide medication name, indications, contraindications, medication form, dosage, administration, actions, side effects, and reassessment on medications that EMTs are permitted to administer.

**Assessment Summary**

**RESPIRATORY DISTRESS**
The following are findings that may be associated with breathing difficulty.

**Scene Size-Up**
Is breathing difficulty due to a medical or a traumatic cause? Look for evidence of:
- Mechanism of injury—collision, fall, guns, knives, bruising on chest
- Home or portable oxygen tanks or concentrators indicating chronic respiratory problems
- Alcohol or food that may indicate choking

**Primary Assessment**

**General Impression**
Position of patient: Tripod
Lying flat

**Facial expression:**
- Agitated or confused

**Speech:**
- Patient may gasp for breath between words.

**Mental Status**
- Alert to unresponsive
- Restlessness
- Agitation
- Disorientation

**Airway**
- Inspect for incomplete or partial obstruction
- Crowing and stridor (indicate partial obstruction)
- Gurgling (indicates fluid in the airway; suction required)

**Breathing**
- Signs of inadequate breathing, including poor chest rise and fall, poor volume heard and felt, diminished or absent breath sounds
- Wheezing heard on auscultation

**Assessment Summary**

Assessment Summaries reinforce assessment steps and processes as well as key assessment findings for specific medical and trauma emergencies.
Emergency Care Protocol

Emergency Care Protocols provide concise summaries of emergency care steps to be taken in medical and trauma emergencies.

**STROKE**

1. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. According to the AHA 2010 guidelines, if the SpO₂ reading is less than 94% the patient complains of dyspnea, or signs and symptoms of hypoxia, heart failure, or shock are present, administer oxygen by nasal cannula at 2 to 4 lpm. High-concentration oxygen is no longer considered routine for the stroke patient unless severe signs of hypoxia are present. Always follow your local protocols.
5. Place the patient in a lateral recumbent position if unresponsive and if no spinal injury is suspected. If responsive and no spinal injury is suspected, elevate the head no greater than 30 degrees.
6. Obtain a blood glucose reading if your protocol permits.
7. Transport.
8. Perform a reassessment every 5 minutes.

**Emergency Care Algorithm RESPIRATORY DISTRESS/FAILURE/ARREST**

Emergency Care Algorithms are graphic pathways that visually summarize assessment and care steps for students.
**EMT Skills**

Located at the end of chapters before review material, EMT Skills present step-by-step skill performance procedures for easy reference.

### Administering Nebulized Medications

1. **Complete the primary assessment and assess the patient’s pulse rate and breath sounds.**
2. **Select the correct medication and consult with medical direction for an order to administer the medication.**
3. **Add the medication to the nebulizer chamber.**
4. **Coach the patient to inhale the nebulized medication from the mouthpiece.**
5. **Reassess the patient’s pulse rate and breath sounds.**

### Four-Rescuer Log Roll and Long Spine Board Immobilization

1. **Establish and maintain in-line stabilization. Apply a rigid cervical spine immobilization collar.**
2. **Place a long spine board parallel to the patient. If possible, pad the voids under the head and torso.**
3. **Three rescuers kneel at the patient’s side opposite the board, leaving space to roll the patient toward them.**
4. **The EMT at the head directs the others to roll the patient as a unit onto his side. Assess the patient’s posterior side.**
5. **The EMT at the waist reaches over, grasps the spine board, and pulls it into position against the patient. (This can also be done by a fifth rescuer.) The EMT at the head instructs the rescuers to roll the patient onto the spine board.**
6. **Secure the patient to the board with straps. Loosely tie the wrists together.**
Case Study Follow-up

Scene Size-Up

You have been dispatched to a 31-year-old female patient complaining of difficulty in breathing. A man answers your call and gives you the address you gather your equipment. He indicates that the patient is his wife, Anna Sanders, who has an extremely hard time breathing. You are led up to the third floor of an apartment complex. You do not note any possible hazards, but are looking at how difficult the extraction might be. Upon walking into the apartment you note a young female patient sitting in a tripod position next to the kitchen table.

Primary Assessment

As you start to introduce yourself, the patient begins to speak, gasping for air after each word. You notice that the breathing difficulty is so great that she struggles to say anything. Her skin is moist and slightly pale. You recognize the patient as a person you service your partner to get the stretcher while you continue with the second primary assessment.

Secondary Assessment

You begin to evaluate the difficulty in breathing using the CDRST mnemonic. You ask Anna questions she can answer with a nod or a shake of her head to reduce her need to respond by speaking. Some questions you direct to her husband. You elicit that the breathing difficulty began gradually about 2 hours ago and got progressively worse. She is unable to lie down because this causes her breathing to get much worse, although sitting upright is also uncomfortable. She was given oxygen by the paramedics en route, but none seem to have been the cause. On a scale of 1 to 10, Mrs. Sanders indicates that her difficulty in breathing is about an 8 or 9.

You continue to evaluate her history. The primary symptom is severe difficulty in breathing. Mrs. Sanders has an allergy to penicillin. (You are aware about medications she takes, Mr. Sanders brings in a tripod position next to the kitchen table when the episode began.)

You quickly perform a physical exam. You assess her neck for jugular vein distention. Inspection of her chest and abdomen reveals significant use of the abdominal muscles when exhaling. The breath sounds are diminished bilaterally and you hear wheezing even without using your stethoscope. Her fingernails are slightly cyanotic. You assess the baseline vital signs and find a blood pressure of 150/84, pulse rate decreased to 80 per minute and regular respirations of 24 per minute. Her radial pulse is about 150 per minute. Her skin is moist and slightly pale. You recognize the patient as a person you service a nod or a shake of her head to reduce her need to respond by speaking. Some questions you direct to her husband. You elicit that the breathing difficulty began gradually about 2 hours ago and got progressively worse. She is unable to lie down because this causes her breathing to get much worse, although sitting upright is also uncomfortable. You note a young female patient sitting in a tripod position next to the kitchen table.

Your husband asks if she have any history of asthma and hypertension. Mr. Sanders brings in a tripod position next to the kitchen table when the episode began.)

You quickly perform a physical exam. You assess her neck for jugular vein distention. Inspection of her chest and abdomen reveals significant use of the abdominal muscles when exhaling. The breath sounds are diminished bilaterally and you hear wheezing even without using your stethoscope. Her fingernails are slightly cyanotic. You assess the baseline vital signs and find a blood pressure of 150/84, pulse rate decreased to 80 per minute and regular respirations of 24 per minute. Her radial pulse is about 150 per minute. Your husband asks if she have any history of asthma and hypertension. Mr. Sanders brings in a tripod position next to the kitchen table when the episode began.

The Student Workbook (ISBN 0133371883) is a self-instructional guide, written to reinforce key concepts presented in the textbook. Every chapter includes five basic sections: Objectives, Key Ideas, Terms and Concepts, Content Review, and Case Study. Two additional sections appear as appropriate in many of the chapters. These special sections are Medical Terminology and Documentation Exercise. Medication Cards are also provided at the end of the Workbook.

**Objectives**
Form the basis of each chapter.

**Key Ideas**
Summarize the chapter’s key concepts.

**Terms and Concepts**
Review major terms that are introduced in bold type in the textbook chapter and are listed and defined at the end of the book.

**Content Review**
Presents questions to review understanding of important information and concepts from the textbook chapter.

**Case Study**
Presents one or more realistic scenarios and requires students to apply chapter information to solving patient management problems.

**Medical Terminology**
Provides a chart of chapter-relevant medical terms that are frequently used in emergency care.

**Documentation Exercise**
Presents a real-life emergency-call scenario that is longer and more detailed than the Case Study scenarios. This exercise includes detailed vital signs and other physical exam and patient history information that would be gathered on such a call.

**Medication Cards**
Contain information about the medications that an EMT can administer or assist the patient in administering, with on-line or off-line approval from medical direction.
MyBRADYLab™
www.mybradylab.com

What Is MyBradyLab?
MyBradyLab is a comprehensive online program that gives you the opportunity to test yourself on basic information, concepts, and skills to see how well you know the material. From the test results, the program builds a self-paced, personalized study plan unique to your needs. Remediation in the form of e-text pages, illustrations, animations, exercises, and video clips is provided for those areas in which you may need additional instruction or reinforcement. You can then work through the program until material is learned and mastered. MyBradyLab is available as a standalone program or with an embedded e-text.

MyBradyLab maps objectives created from the National EMS Education Standards for the EMT level to each learning module. With MyBradyLab, you can track your own progress through the entire course. The personalized study plan material supports you as you work to achieve success in the classroom and on certification exams.

How Do Students Benefit?
MyBradyLab helps you:
• Keep up with the new, complex information presented in the text and lectures.
• Save time by focusing study and review on just the content you need.
• Increase understanding of difficult concepts with study material for different learning styles.
• Remediate in areas in which you need additional review.

Key Features of MyBradyLab
Pre-tests and Post-tests Using questions aligned to EMT Education Standards, quizzes measure your understanding of topics and expected learning outcomes.

Personalized Study Material Based on the topic pre-test results, you will receive a personalized study plan highlighting areas where you may need improvement. Study tools include:
• Skills and animation videos.
• Links to specific pages in the e-text.
• Images for review.
• Interactive exercises.
• Audio glossary.
• Access to full chapters of the e-text.

How Do Instructors Benefit?
• Save time by providing students a comprehensive, media-rich study program.
• Monitor student activity with viewable student assignments.
• Provide consistent delivery of material across all courses and instructors.
• Track student understanding of course content in the program Gradebook.
• Increase student retention.
• Meet the needs of the wide range of learners in your classroom.

Where Can Instructors Get More Information?
Contact your local Brady representative or visit www.mybradylab.com for more information.
Emergency Medical Care Systems, Research, and Public Health

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARDS • Preparatory (Content Areas: EMS Systems; Research); Public Health

COMPETENCIES • Applies fundamental knowledge of the EMS system, safety/well-being of the EMT, medical/legal and ethical issues to the provision of emergency care.

Uses simple knowledge of the principles of illness and injury prevention to the provision of emergency care.

OBJECTIVES • After reading this chapter, you should be able to:

1-1. Define key terms introduced in this chapter.
1-2. Describe the key historical events that have shaped the development of the emergency medical services (EMS) system, including:
   a. Lessons learned in trauma care from experiences in the Korean and Vietnam conflicts
   b. Publication of Accidental Death and Disability: The Neglected Disease of Modern Society
   c. Highway Safety Act of 1966
   d. Emergency Medical Services System Act of 1973
   e. Public CPR courses
   f. Publication of the National Emergency Medical Services Education and Practice Blueprint
   g. Publication of EMS Agenda for the Future and The EMS Education Agenda for the Future: A Systems Approach
   h. Development of National EMS Core Content, National EMS Scope of Practice Model, and National EMS Education Standards
   i. The Institute of Medicine report The Future of EMS Care: EMS at the Crossroads
   j. Medical direction
   i. Trauma systems
   j. Evaluation

1-4. Discuss the differences between 911 and non-911 EMS access systems, including the features and benefits of 911 systems.

1-5. Compare and contrast the scopes of practice of the following levels of EMS providers:
   a. Emergency Medical Responder (EMR)
   b. Emergency Medical Technician (EMT)
   c. Advanced Emergency Medical Technician (AEMT)
   d. Paramedic

1-6. Explain the importance of the EMT’s understanding of the health care resources available in the community.

1-7. Give examples of how EMTs can carry out each of the following roles and responsibilities:
   a. Personal safety and the safety of others
   b. Patient assessment and emergency care
   c. Safe lifting and moving
   d. Transport and transfer of care
   e. Record keeping and data collection
   f. Patient advocacy

1-8. Describe the expectations of EMTs in terms of each of the following professional attributes:
   a. Appearance
   b. Knowledge and skills
   c. Physical demands
   d. Personal traits
   e. Maintaining certification and licensure

continued
1-9. Discuss the purposes of medical direction/oversight in the EMS system.
1-10. Describe the purpose of quality improvement/continuous quality improvement programs in EMS.
1-11. Explain the EMT’s roles and responsibilities in quality improvement.
1-12. Identify activities in EMS that pose a high risk of mistakes and injuries.
1-13. Discuss steps that you can take to minimize mistakes and injuries in EMS.
1-14. Discuss the steps of evidence-based decision making.
1-15. Explain the limitations of evidence-based decision making in EMS.
1-16. Describe the relationship between EMS and public health.
1-17. List the ten greatest public health achievements in the United States in the 20th century.

**KEY TERMS**  • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

| Advanced Emergency Medical Technician (AEMT) p. 5 | evidence-based medicine p. 12 |
| Americans with Disabilities Act (ADA) p. 6 | medical direction p. 11 |
| Emergency Medical Responder (EMR) p. 5 | medical director p. 11 |
| Emergency Medical Technician (EMT) p. 5 | medical oversight p. 11 |
| EMS system p. 3 | off-line medical direction p. 11 |
| | on-line medical direction p. 11 |
| Paramedic p. 5 | prehospital care p. 6 |
| | protocols p. 11 |
| | quality improvement (QI) p. 11 |
| | standing orders p. 11 |

**Case Study**

**The Dispatch**
EMS Unit 121—respond to 10915 Pine Lake Road in Perry Township—you have an elderly male at that location—victim of a fall—Perry Township Fire Department has been notified and is on route—time out 1032 hours.

**En Route**
While you confirm the address with dispatch, your partner pulls out the county map. “I know that location,” he says. “Yes, here. We need to head north on Lincoln.” You pull your unit out of the garage. Your partner operates the emergency lights and sirens. Within 8 minutes, you turn onto Pine Lake Road and spot a police car and a fire truck.

**Upon Arrival**
You position your ambulance in the driveway of the residence to afford an easy exit. As you leave the unit, the police officer—a First Responder who radioed for EMS help—tells you that a 65-year-old male fell about 30 feet down a very steep embankment behind his house. He’s been at the bottom for about 30 minutes. The patient, Edgar Robinson, is conscious and able to tell you that his right arm and leg are injured. The rescue squad from the fire department is preparing to rappel down the embankment to extricate the patient.

**How would you proceed?**
During this chapter, you will read about the roles and responsibilities of an EMT. Later, we will return to the case study and put in context some of the information you learned.

**INTRODUCTION**

One of the most critical health problems in the United States today is the sudden loss of life and disability caused by catastrophic accidents and illnesses. Every year thousands of people in this country die or suffer permanent harm because of the lack of adequate and available emergency medical services. As an Emergency Medical Technician (EMT), you can make a positive difference.

This course is designed to help you gain the knowledge, skills, and attitudes necessary to be a competent, productive, and valuable member of the Emergency Medical Services (EMS) team. As you begin, your instructor will provide the necessary paperwork, describe the expectations for the course and the job, inform you of required or available immunizations, and outline your state and local provisions for certification as an EMT.

**THE EMERGENCY MEDICAL SERVICES SYSTEM**

**A Brief History**
Emergency medical care has developed from the days when the local funeral home was the ambulance provider and patient care did not begin until arrival at the hospital. By contrast, the modern, sophisticated
The modern EMS system has evolved from its beginnings in the 1960s when the President’s Committee for Traffic Safety identified a need to reduce the injuries and deaths related to highway crashes. In 1966, the National Academy of Sciences National Research Council published a report entitled Accidental Death and Disability: The Neglected Disease of Modern Society. This report became known as the “white paper,” detailing the number of deaths and injuries related to traffic crashes in the United States. The “white paper” also identified severe deficiencies in the delivery of prehospital care in the United States and made recommendations intended to change ambulance systems, training requirements, and the provision of prehospital care. The following are some of the significant developments that have had a profound effect on emergency medical services:

- The Highway Safety Act of 1966 required each state to establish a highway safety program that met prescribed federal standards and included emergency services. The Department of Transportation, through its National Highway Traffic Safety Administration (NHTSA), took a leadership role in the development of emergency medical services. An early focus was improving the education of prehospital personnel. One initiative was the development of national standard curricula. The EMT programs of today have gradually evolved from this charge and continue to use a national standard curriculum.

- The Emergency Medical Services System Act of 1973 provided access to millions of dollars of funding geared to EMS system planning and implementation, personnel availability, and training.

- The American Heart Association began to teach cardiopulmonary resuscitation (CPR) and basic life support to the public. Completion of a CPR course is now a prerequisite to the EMT course.

- The National Registry of EMTs in 1993 released the National Emergency Medical Services Education and Practice Blueprint, which defined issues related to EMS training and education and was intended to guide the development of national training curricula.

- The National Highway Traffic Safety Administration in 1996 published the EMS Agenda for the Future document with the intent to make EMS a greater component in the health care system in the United States. In 2000, a follow-up document, The EMS Education Agenda for the Future: A Systems Approach, was released to address the issue of consistency in the education, training, and certification and licensure of entry-level EMS personnel nationally.

- The National Highway Traffic Safety Administration and Health Resources and Services Administration in 2005 published the National EMS Scope of Practice, which defined the domain of knowledge found in the National EMS Scope of Practice Model. It promotes universal knowledge and skills for EMS personnel.

- The National Highway Traffic Safety Administration in 2006 published The National EMS Scope of Practice Model, which defines four levels of EMS licensure and the corresponding knowledge and skills necessary at each level. The Scope of Practice will be discussed later in the chapter.

- The Institute of Medicine report The Future of EMS Care: EMS at the Crossroads in 2006 recommended that all state governments adopt a common scope of practice that allows for reciprocity between states, national accreditation for all paramedic programs, and national certification as a prerequisite for state licensure and local credentialing.

- The National Highway Traffic Safety Administration’s National EMS Education Standards outline the minimum terminal objectives for entry-level EMS personnel based on the National EMS Scope of Practice Model. The contents of this textbook are based on the National EMS Education Standards.

Advances continue to be made in emergency medical services design and response, equipment, research, and the education of EMTs. Many lives have been saved and unnecessary disabilities avoided because of these advances in emergency medical services.

**Technical Assistance Program Assessment Standards**

Each state has control of its own EMS system, independent of the federal government. However, the National Highway Traffic Safety Administration (NHTSA) provides a set of recommended standards called the “Technical Assistance Program Assessment Standards.” A brief description of these standards follows. They will...
be discussed in much more detail throughout this text and in your EMT course.

- Regulation and policy. Each state must have laws, regulations, policies, and procedures that govern its EMS system. A state-level EMS agency is also required to provide leadership to local jurisdictions.

- Resource management. Each state must have central control of EMS resources so that each locality and all patients have equal access to acceptable emergency care.

- Human resources and training. All personnel who staff ambulances and transport patients must be trained to at least the EMT level.

- Transportation. Patients must be provided with safe, reliable transportation by ground or air ambulance.

- Facilities. Each seriously ill or injured patient must be delivered in a timely manner to an appropriate medical facility.

- Communications. A system of communications must be in place to provide public access to the system and communication among dispatcher, EMS personnel, and hospital.

- Public information and education. EMS personnel should participate in programs designed to educate the public in the prevention of injuries and how to properly and appropriately access the EMS system.

- Medical direction. Each EMS system must have a physician as a medical director to provide medical oversight that includes overseeing patient care and delegating appropriate medical practices to EMTs and other EMS personnel.

- Trauma systems. Each state must develop a system of specialized care for trauma patients, including one or more trauma centers and rehabilitation programs, plus systems for assigning and transporting patients to those facilities.

- Evaluation. Each state must have a quality improvement system for the continuing evaluation and upgrading of the system.

**Access to the EMS System**

There are two general systems by which the public can access emergency medical services: 911 and non-911.

Often referred to as the universal number, 911 is the phone number used nationwide to access emergency services, including police, fire, and EMS. The most common 911 system is enhanced. An enhanced 911 system, called E-911, provides automatic number identification (ANI) and automatic location identification (ALI), which indicate the exact address and phone number from which the call is being made. This information is automatically displayed on the computer screen of the call taker, even if the individual making the call hangs up. The main advantage of E-911 is that the address and phone number are automatically displayed, and an immediate response can be dispatched, even if the caller is unable to communicate effectively—for example, because of an injury or illness such as a stroke, or if he cannot recite his address in the confusion of the emergency, or if it is a child who cannot tell the call taker the address.

While exact procedures may vary, the basic process is the same. Calls are received by a public service answering point (PSAP) where a call taker collects, verifies, and records the information about the emergency, decides which service must respond, and facilitates alerting the necessary service (Figure 1-1).

There are two main benefits to the 911 universal number:

- The public service answering point is generally staffed by trained communications personnel. Many are specially trained as Emergency Medical Dispatchers (EMDs), who not only take the call and facilitate the dispatch of emergency services but also provide instructions for lifesaving emergency care, such as bleeding control or CPR, that can be administered immediately by the caller or another person at the scene.

- The use of 911 reduces the time it takes the caller to access the emergency services system. The caller does not have to look up a ten-digit number to contact in the case of an emergency. The number is easy for young children to remember and dial. All three services—police, fire, and EMS—are accessible by dialing one number. Thus, all emergency resources can be dispatched simultaneously to a scene, for example, to a car crash that requires traffic control and investigation by the police, fire suppression and extraction by the fire service, and emergency medical care and transportation by EMS.

The Federal Communication Commission (FCC) currently estimates that wireless (cell) phones are responsible for placing approximately 70 percent of 911 calls, with the percentage increasing each year. Although wireless phones are an extremely important tool in gaining access to public safety services in the event of an emergency, they also provide unique challenges to the public service answering point and the information shared with
the call taker. Because wireless service is mobile and not associated with one fixed address or geographic location, the cell site (tower) closest to the 911 caller is often the only location identifier. Also, the call can be erroneously sent to a PSAP that doesn’t service that particular area if the cell site is close to a geographic boundary.

The FCC has adopted rules to improve the accuracy of location information provided to PSAPs by wireless technology companies. These rules include:

- **Basic 911**: The wireless service provider to transmit all calls to a PSAP regardless of whether or not the caller subscribes to the provider’s service.
- **Phase I Enhanced 911**: The wireless service provider must provide the PSAP with the telephone number of the device placing the call and the location of the cell site or base station transmitting the call.
- **Phase II Enhanced 911**: The wireless service provider must provide the latitude and longitude of the caller. The information must be accurate within 50 to 300 meters, depending on the type of technology used.

Technology to track the exact location of cell phone calls through global-positioning-satellite (GPS) has been developed and is now being used by many, but not yet all, EMS systems.

Voice over Internet Protocol (VoIP) services have also presented challenges to accessing 911 in an emergency. The FCC imposed requirements that VoIP providers must provide 911 service to all customers as a standard feature, obtain a physical location from the subscriber of where the service will be used, and transmit all 911 calls, including callback number and registered location, to the appropriate public service answering point.

**Levels of Training**

The *National EMS Scope of Practice Model* released by the National Highway Traffic Safety Administration in 2005 was developed to bring a higher degree of consistency to EMS throughout the United States, improve patient care and safety, allow for easier reciprocity between states, and decrease public confusion by identifying specific national levels of EMS practitioners. The National Scope of Practice Model identifies the following four levels of EMS practitioners (Figure 1-2).

1. **Emergency Medical Responder (EMR)**, which is similar to the First Responder level, provides immediate lifesaving care to patients who have accessed the EMS system and while awaiting response from a higher-level EMS practitioner. The EMR uses basic airway, ventilation, and oxygen therapy devices; takes patient vital signs; and provides stabilization of the spine and suspected extremity injuries, eye irrigation, bleeding control, emergency moves, CPR, automated external defibrillation, and emergency childbirth care.

2. **Emergency Medical Technician (EMT)** provides basic emergency medical care and transportation to patients who access the EMS system. The interventions provided by the EMT include those performed by the EMR but with basic equipment found on an ambulance. The EMT level is similar in scope to the EMT-Basic level with the addition of advanced oxygen therapy and ventilation equipment, pulse oximetry, use of automatic blood pressure monitoring equipment, and limited medication administration.

3. **Advanced Emergency Medical Technician (AEMT)** provides both basic and limited advanced emergency medical care and transportation to patients in the prehospital environment. The AEMT provides all of the skills of the EMT with the addition of the use of advanced airway devices, monitoring of blood glucose levels, initiation of intravenous and intraosseous (in-the-bone) infusions, and administration of a select number of medications.

4. **Paramedic** scope of practice includes the skills performed by the EMT and AEMT with the addition of more advanced assessment and patient management skills and provision of the highest level of prehospital care. Paramedics perform advanced assessments, form a field impression, and provide invasive and drug interventions as well as transport. Their care is designed to reduce disability and death of patients who access the EMS system.

**The Health Care System**

First Responders and EMTs are an integral part of a community’s health care system—a network of medical care that begins in the field and extends to hospitals
and other treatment centers. In essence, EMTs provide **prehospital care**—emergency medical treatment given to patients before they are transported to a hospital or other facility. (In some areas the term **out-of-hospital care** is preferred, reflecting a trend toward providing care on the scene with or without subsequent transport to a hospital. Out-of-hospital care also includes care provided during interfacility transport. Your instructor can provide information on how or if this term may apply to your EMS system.)

The EMT may be required to decide on the facility to which the patient must be transported. The most familiar destination is the hospital emergency department, which is staffed by physicians, nurses, and others trained in emergency medical treatment. Here patients are stabilized and prepared for further care. Some patients may need to be transported to special facilities such as the following:

- **Trauma center** for rapid surgical intervention and specialized treatment of injuries that generally exceed hospital emergency department capabilities (Figure 1-3 ■).
- **Burn center** for specialized treatment of serious burns, often including long-term care and rehabilitation
- **Obstetrical center** for high-risk obstetric patients
- **Pediatric center** for specialized treatment of infants and children
- **Poison center** for specialized treatment of poisoning victims
- **Stroke center** to provide specialized care for specific acute stroke patients
- **Cardiac center** for the rapid and advanced management of patients suffering cardiac emergencies
- **Hyperbaric center** for the treatment of certain toxic exposures, diving emergencies, and other conditions
- **Spine injury center** for the management of patients with severe spine injuries
- **Psychiatric center** to care for patients with behavioral emergencies

You will often be called to emergencies where you and your partner are the only trained emergency personnel involved. At other times, two or more emergency services will be needed at the scene (Figure 1-4 ■). Specialized rescue teams and fire personnel, as well as law enforcement, all may be involved. As a member of the team that stabilizes and transports a patient (Figure 1-5 ■), you will be in a position to serve as the liaison between the community’s medical services and those public safety workers.

**THE EMT**

**Roles and Responsibilities**

While specific responsibilities may vary from one area to another, your general responsibilities as an EMT include personal safety and the safety of others, patient assessment and emergency medical care, safe lifting and moving, patient transport and transfer, record keeping and data collection, and patient advocacy. These and other responsibilities are found in Table 1-1. All of these will be covered in greater detail in later chapters.

In light of these roles and responsibilities, the **Americans with Disabilities Act (ADA)** of 1990 protects
Drive safely at all times, using proper precautions to avoid traffic accidents. Use a seat belt whenever you drive or ride, unless you need to remove it to care for the patient. Remove yourself from potentially hazardous sites such as high-traffic areas, downed power lines, gasoline leaks, fires, chemical spills, radiation leaks, and so on. Never enter a volatile crowd situation, such as a riot, crime scene, or hostage situation, until it has been controlled by law enforcement. Take extra precautions when you suspect that a patient, relative, or bystander at the scene is under the influence of drugs or alcohol, has a behavioral disorder, or is emotionally charged, because these individuals have a tendency to suddenly change their behavior and may become a danger to you and your crew.

At the scene, follow directions from police, fire, utility, and other expert personnel. Create a safe area in which the patient can be treated (away from the threat of fire or explosion, for example). Redirect traffic for the safety of patients and bystanders.

Wear reflective emblems or clothing at night, and provide adequate lighting at an accident scene. Minimize personal injury from jagged metal or broken glass at an accident scene by wearing a helmet or hard hat, protective outerwear, eye protection, and leather gloves. In addition, wear protective gear, such as gloves, eye protection, mask, and gown, as necessary to avoid infectious diseases.

**Personal Safety and the Safety of Others**

Your first and most important priority is to protect your own safety (Figure 1-6). Remember this rule: You cannot help the patient, other rescuers, or yourself if you are injured. You also do not want to endanger other rescuers by forcing them to rescue you—instead of the patient. Once scene safety is ensured, the patient’s needs become your priority.

Once you have ensured scene safety, you must gain access to patients, recognize and evaluate problems, and provide emergency care (Figure 1-7)—often in situations that involve more than one patient. First, always perform a primary assessment to help you identify and
care for immediately life-threatening problems, such as airway compromise, respiratory insufficiency, cardiac arrest, or severe bleeding. Then complete a secondary assessment, after which you can stabilize and treat other emergency injuries or conditions you discover or suspect. Work as quickly as possible while avoiding undue haste, carelessness, and mishandling of the patient. Always be aware of changing conditions and ensure that the scene remains safe.

**Safe Lifting and Moving**

Prevent further injury of patients by always using the easiest and safest recommended emergency urgent or nonurgent moves and equipment. Prevent injuring yourself by always using proper body mechanics and by making sure you have sufficient help to lift and move patients and equipment.

**Transport and Transfer of Care**

Before leaving the scene, determine which facility (local emergency department, pediatric hospital, burn center, or other) will be most appropriate. Consider the patient’s condition, the extent of injuries, prior health care contact, the relative locations, hospital staffing, and destination protocols when making transport decisions. Consult medical direction if necessary, and follow your local transport protocols.

Use the communications equipment available to you to notify the receiving facility of the number of patients, the destination(s), and the nature and extent of injuries. Alert the emergency department or receiving facility about high-priority patients and what will be needed immediately upon arrival, such as a trauma team or a stroke team. Report changes in the patient’s condition, and consult medical direction during transport as appropriate and as required (Figures 1-8■ and 1-9■).

Drive in a way that will minimize further injury and maximize patient comfort. Obey appropriate laws and regulations, and use lights and sirens properly. Realize that not all patients require the use of lights and sirens. Once you reach the destination, help remove the wheeled stretcher and maneuver it into the emergency department.

Report both verbally and in writing to the appropriate receiving facility personnel what injuries or conditions were identified, what care has been given to the patient, and the patient’s response to treatment. Provide other assistance as needed and do not leave before the patient has been properly transferred to the care of the receiving facility personnel (Figure 1-10■).

**Record Keeping and Data Collection**

Throughout your shift, maintain an up-to-date log of calls, if required. Before leaving the hospital, or as soon as possible, complete the written or electronic prehospital care report (Figure 1-11■). A copy of this report will become part of the patient’s medical record and part of your EMS system’s permanent records.

**Patient Advocacy**

As an emergency care provider, you are also responsible for protecting the patient’s rights. At the scene, collect and safeguard a patient’s valuables on his person,
Knowledge and Skills

To practice as an EMT, you need to successfully complete the basic training program for EMTs as outlined by the U.S. Department of Transportation. In addition to the required course work, you also need to know the following:

- **Use and maintenance of common emergency equipment**, such as suction machines, oxygen-delivery systems, airway adjuncts, automated external defibrillators, spinal immobilization equipment, splints, obstetrical kits, various types of patient-moving devices, and tools to gain access to the patient.
- **Assistance with the administration of medications** approved by medical direction.
- **Cleaning, disinfection, and sterilization of nondisposable equipment**.
- **Safety and security measures** for yourself, your partner, and other rescuers, as well as for the patient and bystanders.
- ** Territory and terrain** within the service area to allow expedient response to the scene and to the appropriate receiving facility.
- **State and local traffic laws and ordinances** concerning emergency transportation of the sick and injured. Ambulances are given certain privileges, but they are not immune from all traffic laws.

Use opportunities for continuing education to expand your knowledge and learn about advances in patient care, new equipment, or better ways of using existing equipment. Take refresher courses to renew your knowledge and skills. Finally, maintain up-to-date knowledge of local, state, and federal legislation, regulations, standards, guidelines, and issues that affect the emergency medical systems in your area.

Physical Demands

To be an EMT, you must be in good physical health. You must be able to lift and carry up to 125 pounds.
Your eyesight must be good (correction by lenses is permitted), and you must have good color vision in order to properly assess a patient as well as for driving safely. Color vision is necessary to determine various changes in the color of the skin, nail beds, lips, and inside the mouth, which provide critical information about the severity and the possible condition the patient is experiencing. You must also be able to communicate effectively both orally and in writing. This will be necessary when communicating with patients, crew members, other emergency response personnel, and the medical staff. Your hearing must be good enough to accurately hear radio communications, patient and bystander responses, auscultated blood pressure, auscultated and other abnormal patient noises, communication from other crew members at the scene, and oral instructions.

**Personal Traits**

In times of crisis, patients will look toward someone to reestablish order in a suddenly chaotic world. Chances are that someone will be you. It can bring out the best in you as well as cause you a great deal of stress. To be effective as an EMT, you should have the following characteristics:

- **A calm and reassuring personality.** As an EMT you will often be required to perform skills and procedures while speaking in a reassuring and calming voice to a patient who may be agitated, in shock, or in a great deal of pain.
- **Leadership ability.** You must be able to assess a situation quickly, step forward to take control when appropriate, set action priorities, give clear and concise directions, be confident and persuasive enough to be obeyed, and carry through with what needs to be done.
- **Good judgment.** You must be able to make appropriate decisions quickly, often in unsafe or stressful situations involving human beings in crisis.
- **Good moral character.** While there are many legal constraints on the profession, you also have ethical obligations. You are in a position of public trust that can never be wholly defined by statute or case law alone.
- **Stability and adaptability.** Being an EMT can be quite stressful. Exhaustion, frustration, anger, and grief are part of the package. You must learn how to delay expressing your feelings until the emergency is over. Just as important, you must also understand that intense emotional reactions are normal and that seeking support from coworkers, counselors, friends, and family is an important aspect of keeping yourself mentally and physically fit.
- **Ability to listen.** You must be an effective listener when gathering information from patients and bystanders and when receiving orders from medical direction or others at the scene. You should exhibit empathy and compassion in your responses; however, you must always maintain a high degree of professionalism, confidence, and competence.
- **Resourcefulness and ability to improvise.** You will find yourself in some situations where a particular piece of equipment, tool, or technique doesn’t quite work. You will need to be resourceful, quickly thinking and adapting to make things work for the best care for your patient. You will find yourself improvising to care for and move some patients. As an example, if a patient entrapped in an overturned vehicle needs immediate ventilation, you must determine the most effective method to gain entry to the vehicle, to provide ventilation with both you and the patient in an awkward and unusual position, and to continue to deliver ventilation while removing the patient from the wrecked vehicle. Each call, situation, and patient is different and requires quick thinking and resourcefulness to provide efficient and effective emergency care.
- **Cooperativeness.** Often your call may involve other emergency services, such as First Responders and the police. You must be able to act as a leader while fully cooperating with others at the scene to provide the best possible care to the patient.

**Maintenance of Certification and Licensure**

It is the personal responsibility of each EMT to maintain certification and licensure to practice. This involves meeting the necessary continuing education requirements, verifying skill competency, avoiding any criminal or unethical behavior, and submitting all fees necessary to maintain current certification and licensure.

**State EMS Agency Role**

According to the National Association of State EMS Officials (NASEMSO), every state and territory in the United States has a lead EMS agency. The primary responsibilities of the state EMS agency are:

- Overall planning of the statewide EMS system
- Coordination of the statewide EMS system
- Regulation of the statewide EMS system
- Licensing local EMS agencies and personnel

As EMS continues to evolve, there is often overlap between the emergency medical services, public safety, and public health. The state EMS agency is actively involved in ensuring that a high quality of emergency medical services is provided in order to protect the health and safety of the public.
Medical Direction/Medical Oversight

As an EMT, you are the designated agent of the physician medical director of your EMS system. The care you render to patients is considered an extension of the medical director’s authority. (Learn your own state laws, statutes, and regulations in regard to medical direction.)

The **medical director** is a physician who is legally responsible for the clinical and patient care aspects of the EMS system. An EMS medical director is also involved in EMS education programs and refresher courses, overseeing and providing continuing education, and facilitating the quality improvement system. Every emergency medical service must have a medical director in order to provide any level of prehospital care.

The medical director is responsible for providing **medical direction**. A primary charge of medical direction is developing and establishing the guidelines under which the emergency medical service personnel function. These guidelines are referred to as **protocols**. Protocols comprise a full set of guidelines that define the entire scope of medical care (triage, treatment, transport, destination). Often referred to as orders, protocols may consist of both off-line and on-line medical direction.

**Off-line medical direction** is provided through a set of predetermined, written guidelines that allow EMTs to use their judgment to administer emergency medical care according to the written guidelines without having to contact a physician. **On-line medical direction** requires that the EMT acquire permission from a physician via cell phone, telephone, or radio communication prior to administering specific emergency care. As an example, the protocol for chest pain may read: (1) Administer oxygen via nonrebreather mask at 15 lpm; (2) place patient in position of comfort; (3) administer one patient-prescribed nitroglycerin tablet if systolic blood pressure is greater than 90 mmHg; (4) administer one 160–325 mg aspirin; (5) contact advanced life support; (6) if the patient does not experience relief of chest pain from one nitroglycerin tablet, contact medical direction to consider administering additional doses.

Items 1 through 5 are all off-line medical direction or standing orders. The EMT is expected to perform these treatments and activities for a patient having chest pain without having to contact the physician prior to treatment. However, in reference to item 6, if the patient is continuing to experience chest pain, the EMT must contact medical direction and receive permission to administer any additional doses of nitroglycerin. Because item 6 requires direct communication with the physician, it is considered on-line medical direction.

**Standing orders** are a subset of protocols that do not require real-time physician input. In some systems, the term is synonymous with off-line medical direction. In some systems, the term **standing orders** refers specifically to treatments that can be performed if communication cannot be established or is lost with medical direction.

**Medical oversight** is the emerging term that more comprehensively describes the EMS system medical director’s responsibilities. These include all of the clinical and administrative functions and activities performed by the medical director as necessary to exercise ultimate responsibility for the emergency care provided by individual personnel and the entire EMS system.

Quality Improvement

**Quality improvement (QI),** also known as **continuous quality improvement (CQI),** is a system of internal and external reviews and audits of all aspects of an emergency medical system. To ensure that the public receives the highest quality of prehospital care, the goals of quality improvement are to identify those aspects of the system that can be improved and to implement plans and programs that will remedy any shortcomings. It is important to recognize that quality improvement is not designed to evaluate individual performance, but instead is intended to determine how effective the system is and to identify what improvements can be made to deliver a better service. Although quality improvement can identify an individual with a poor performance that requires some type of corrective action or remedial work, as a general rule quality improvement should be used not as a penalty tool but as an evaluation system geared toward overall system improvement.

As an EMT, your role in quality improvement (Figure 1–12 ▶) is to:

- **Document carefully.** Carefully and thoroughly document each call. Prehospital care reports that you prepare are studied by quality improvement committees to spot such things as excessive response times, which might be remedied by redeploying ambulances, or to identify seldom-used skills for refresher training.
- **Perform reviews and audits.** Become involved in the quality improvement process by volunteering for QI committee work or by critiquing the performance of other EMTs at the scene of a call.
- **Obtain feedback.** Gather feedback from patients, other EMS personnel, and hospital staff. This may be done formally through surveys distributed to patients and hospital staff members, or informally by seeking advice about your performance after a call from physicians, nurses, or other medical personnel.
- **Maintain equipment.** Conduct preventative maintenance on equipment and ensure it is in the proper working order.
- **Participate in continuing education.** Participate in refresher courses and continuing education to reinforce, update, and expand your knowledge and skills.
- **Maintain skills.** It is important to continuously practice your skills to a level of mastery.
You can take the following steps to prevent errors that may jeopardize the patient’s safety:

- Develop clear protocols.
- Light the scene effectively.
- Try to minimize interruptions during assessment and emergency care.
- Clearly mark all drugs and packages so each is very distinct.
- Reflect on all actions.
- Question all assumptions.
- Use decision aids if necessary.
- Ask for assistance if you need it.

## RESEARCH AND EMS CARE

The traditional approach to the practice of medicine involved a combination of a strong foundation of scientific knowledge, intuition, and good judgment. As medical practice has evolved, the science component has become more emphasized through the concept of evidence-based medicine. Evidence-based medicine focuses on research to provide clear evidence that certain procedures, medications, and equipment improve the patient’s outcome. The following four steps are common in evidence-based decision making:

- Formulate a question about emergency care that needs to be answered.
Search medical literature for research data that are related and applicable to the question.

Appraise the evidence for validity and reliability.

If the evidence supports a change in practice, change protocols and implement the change in prehospital emergency care.

Although an evidence-based approach appears to be extremely desirable in making decisions about prehospital patient management, very little research has so far been done regarding prehospital care. EMS has typically had to rely on research conducted for the hospital emergency department. Although hospital and prehospital emergency care are somewhat related, there are variables in the prehospital environment that are not encountered in the hospital setting; thus, it is often difficult to extrapolate and apply the results and conclusions of hospital emergency care research to prehospital practice.

Initiatives are under way to increase the amount of research conducted specifically to support or to change the delivery of prehospital emergency care. It is the responsibility of every EMT to participate in such research so that EMS can develop its own evidence-based practices to support and improve its profession.

PUBLIC HEALTH

The majority of the EMT's responsibilities are concerned with treating patients who have a medical illness or traumatic injury. However, as an EMT you are also part of the public health team. Public health deals with protecting the health of an entire population. Specific populations will be defined differently depending on the issue at hand. The population under consideration may be a select group, such as children, elderly adults, individuals with mental or physical disabilities, a neighborhood, a city, a state, or an entire nation.

Public health is first responsible for identifying problems that affect the health of the population in question. As an example, the lack of the use of infant and child car seats in a particular region as identified through injury surveillance data would prompt the public health professional to take action. EMTs may be the frontline individuals in identifying the problem, reporting on the issue to the proper agency, and potentially providing education to those who are involved in the problem.

Public health attempts to reduce the incidence of injury and illness through preventative strategies geared at protecting, promoting, and improving the health of a population. This is typically achieved through research, education, and health promotion. In published statements, the American Public Health Association has defined the vision of public health as “to promote physical and mental health and prevent disease, injury, and disability.”

According to the Centers for Disease Control (CDC) Morbidity and Mortality Weekly Report, the ten greatest public health achievements in the United States in the 20th century were:

- **Vaccinations** to eliminate smallpox and polio, and to control measles, rubella, tetanus, diphtheria, *Hae-mophilus influenzae* type B, and other infectious diseases
- **Motor-vehicle safety** measures to reduce the number of motor-vehicle deaths
- **Workplace safety** measures to decrease the number of work-related deaths
- **Control of infectious disease** through clean water and sanitation and antimicrobial therapy
- **Reduction in deaths from coronary heart disease and stroke** related to the reduction in risk factors such as smoking and high blood pressure
- **Safer and more healthful foods** through controlling food contamination and ensuring the nutritional value of foods
- **Decline in maternal and infant mortality** through better hygiene, nutrition, antibiotics, access to health care, and technologic advances in maternal and infant care
- **Use of barrier devices during sexual contacts** to protect against pregnancy, HIV, and other sexually transmitted diseases
- **Fluoridation of drinking water** to prevent tooth decay and tooth loss
- **Reduction in the use of tobacco products** through promotion of cessation programs and reduction of secondhand smoke, resulting in improvement across a wide spectrum of health issues

Public health professionals may be involved in enforcing laws and regulations that protect the health and ensure the safety of the public. This may be achieved through legislation such as seat belt and helmet laws.

EMS is part of the public health system and plays an integral role in carrying out its mission. Roles of EMS in public health include:

- Health prevention and promotion through primary prevention (vaccinations, education), secondary prevention of complications of disease, and health screening (Figures 1-13a, b and c)
- Disease surveillance through identifying and reporting certain diseases or conditions that are identified as public health issues
- Injury prevention through education, promotion of the use of safety equipment (seat belt use, helmet use, falls prevention, fire prevention), and injury surveillance
Emergency medical services systems have evolved dramatically from the days when the funeral home provided transportation of the sick and injured to the hospital as a courtesy. Many of the practices today have come from treating military casualties on the battlefield during various wars and conflicts. Because of the number of highway deaths associated with auto crashes, the Department of Transportation in the 1960s took a lead role in developing the education program for EMTs. Even though EMS systems are independent of federal government control, the National Highway Traffic Safety Administration (NHTSA) developed the Technical Assistance Program Assessment Standards as recommended guidelines for EMS systems.

Most EMS systems are accessed using the universal number 911. Quick access via this standardized number reduces response times. Enhanced 911 systems provide the name, geographic location, and phone number for the landline the call is being made from.

The levels of EMS training according to the National Scope of Practice Model are Emergency Medical Responder (EMR), Emergency Medical Technician (EMT), Advanced EMT (AEMT), and Paramedic.

The EMT has many roles and responsibilities: safety, patient assessment and emergency care, transportation and transfer of care, patient advocacy, professional appearance, knowledge and skills, ability to handle physical demands, and positive personal traits. Many of these roles and responsibilities are essential to the function of the EMT.
Medical direction or medical oversight is a key component of any EMS system. An EMT is unable to function without medical direction. One responsibility of medical direction is to provide orders or protocols. Medical direction may be off-line, in the form of written patient care orders, or on-line, where you communicate directly with the physician or a designee for oral patient care orders.

To improve the EMS system, quality improvement (QI) must be performed to identify any weaknesses or inadequacies. QI is a continuous process that involves all aspects of the system, including the personnel who provide care.

Emergency care provided in the prehospital environment is continuously evolving based on current research. Treatments and techniques that were used in the past have been supported, changed, or eliminated based on evidence found in studies. New techniques and treatments are no longer implemented without adequate evidence to support their effectiveness. More research needs to be conducted that is specific to EMS.

Emergency medical services is part of the public health system, vision, and mission. EMS is on the frontline to reduce the incidence of injury and illness through preventative strategies that are geared toward protecting, promoting, and improving the health of a population. This is typically achieved through education, health and safety promotion, and research.

---

**Case Study Follow-up**

**Scene Size-up**

You have been dispatched to a 65-year-old male, Edgar Robinson, who fell down a steep embankment behind his house. Although the rescue squad officer informs you that you will be in no personal danger, you and your partner are cautious as you carry your equipment closer to the embankment. As your partner takes the patient’s wife, Mrs. Robinson, aside, the rescue squad officer tells you that his crew all have Emergency Medical Responder training and will immobilize Mr. Robinson on a backboard before bringing him up.

**Primary Assessment**

One Emergency Medical Responder reports her observations of the patient to you as the others place the patient where you indicate. She tells you that the patient’s chief complaint is of pain to his right wrist and right thigh and that the patient’s airway is patent with respirations of 24 per minute with an adequate volume, radial pulse is 90 beats per minute and strong, and the skin is warm and dry.

As you begin your own primary assessment, you note that your general impression of Mr. Robinson is of an alert, robust older man. Mr. Robinson explains to you that while disposing of yard wastes, he got too close to the edge of the embankment and slipped.

**Secondary Assessment**

You perform a physical exam while your partner takes vital signs, which indicate no change from those reported by the Emergency Medical Responder. Your physical exam reveals abrasions to the arms, with pain and a slight deformity to the right wrist. There are also superficial abrasions to the right leg, with deformity, swelling, and pain to the right thigh. You discover that the patient cannot feel or move the toes of his right foot. However, pulses are present in the foot.

You initiate oxygen therapy via a non-rebreather mask. The history you take, by asking questions of the patient, confirms sharp pain to the right wrist and thigh, which started immediately after he landed at the bottom of the embankment. Mr. Robinson also reports that he did not lose consciousness. He denies any other complaints but informs you that he is allergic to sulfa drugs and takes medication for high blood pressure.

After checking the immobilization of the patient, you enlist the Emergency Medical Responders to help you apply a traction splint to the right leg. Then you splint the injured wrist. During these procedures, you speak quietly and reassuringly to the patient.

**Reassessment**

You move Mr. Robinson on the backboard to a wheeled stretcher, then transfer him to the ambulance. You notify the hospital that you are en route and give details of the patient’s condition, then conduct a reassessment every 5 minutes to monitor his condition until you arrive at the hospital.

Upon arrival, you transfer care of the patient without incident to the emergency department staff and give your verbal report. You carefully complete your written prehospital care report and prepare the unit for the next call.
IN REVIEW

1. Describe the purpose of the modern EMS system.
2. Name two ways the public accesses the EMS system. Explain advantages or disadvantages of each.
3. List the four levels of prehospital emergency care training.
4. List six types of special facilities, other than a hospital emergency department, to which some patients may need to be transported.
5. List the general responsibilities of an EMT.

6. Describe at least five steps you can take to protect your own safety as an EMT.
7. Describe at least three ways you might act as the patient’s advocate.
8. Describe the EMS physician medical director’s primary responsibility.
9. List the goals of quality improvement.
10. Describe the EMT’s role in quality improvement.
11. Describe evidence-based EMS care.
12. Explain the role of the EMT in public health.

CRITICAL THINKING

You are called to the residence of a 78-year-old male patient who appears to have suffered a stroke. The patient is unable to speak and appears agitated. The niece of the patient wants him transported to the small local hospital a few blocks from his house. A stroke center is approximately 20 minutes from your location.

1. What are your responsibilities while on this call?
2. How can you serve as the patient’s advocate?
3. How can you use medical direction in this situation?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARDS • Preparatory (Content Areas: Workforce Safety and Wellness); Medicine (Infectious Diseases)

COMPETENCIES • Applies fundamental knowledge of the EMS system, safety/well-being of the EMT, medical/legal and ethical issues to the provision of emergency care.
  Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

OBJECTIVES • After reading this chapter, you should be able to:

2-1. Define key terms introduced in this chapter.
2-2. Given a description of a patient or family member’s behavior, identify the stage of grief it most likely represents.
2-3. Explain the principles for interacting with patients and family members in situations involving death and dying.
2-4. Give examples of situations that EMS providers may find stressful.
2-5. Compare and contrast the characteristics of acute, delayed, and cumulative stress reactions.
2-6. Recognize signs and symptoms of stress reactions.
2-7. Describe lifestyle changes you can make to help you deal with stress.
2-8. Describe responses your friends and family may have to your work in EMS.
2-9. Describe changes in the work environment that can help you manage job-related stress.
2-10. Discuss the components of a comprehensive system of critical incident stress management.
2-11. Describe measures you can take to protect yourself from exposure to diseases caused by pathogens and accidental and work-related injury.
2-12. Give examples of diseases caused by each of the different types of pathogens (bacteria, viruses, fungi, protozoa, and helminths).
2-13. Describe the Standard Precautions that must be taken to protect health care workers from exposure to infectious diseases.
2-14. Describe the personal protective equipment that may be used by EMS personnel.
2-15. Explain the role of immunizations and tuberculosis testing in maintaining good health.
2-16. Discuss the risks and preventive measures for specific infectious diseases of concern to EMTs, including:
  a. Hepatitis B
  b. Hepatitis C
  c. Tuberculosis
  d. Acquired immune deficiency syndrome
  e. Severe acute respiratory syndrome
  f. West Nile virus
  g. Infections due to multidrug-resistant organisms
2-17. Explain the risks and measures that can be taken to protect yourself against the following hazards:
  a. Hazardous materials
  b. Hazardous rescue situations
  c. Traffic-related injuries
  d. Violence and crime
2-18. Describe the components of physical and mental wellness.
Death and Dying

Death and dying are inherent parts of emergency medical care. You must care for the dying patient’s emotional needs, as well as his injuries or illnesses. If the patient has suffered a sudden death, you may also need to help the family or bystanders deal with the situation.

A study by Elizabeth Kübler-Ross on how people cope with death has identified five general stages that dying patients—and those close to them—will experience. However, each person is unique. Individuals will progress through the stages at their own rates and in their own ways. Although these stages usually apply to the dying patient, they also can apply to patients experiencing nonfatal emergencies. For example, a patient who loses both legs in an industrial accident will grieve the loss of the limbs.

Five Emotional Stages

Characteristically, you will not witness all five stages during emergency treatment. For example, the critically injured patient who is aware that death is imminent typically displays denial, bargaining, or depression. The terminally ill patient may be more prepared and display acceptance. The key for you is to accept all these emotions as real and necessary, and respond accordingly.
Denial (“Not me.”). At first, the patient may refuse to accept the possibility that death is near. This refusal, or denial, is a defense mechanism that creates a buffer between the shock of approaching death and the need to deal with the illness or injury.

Anger (“Why me?”). As the patient moves through denial, anger generally follows—and you may be the target. Do not become defensive. That kind of anger is an aspect of the grieving process both dying patients and their families go through. Be empathetic, and use your best listening and communication skills.

Bargaining (“Okay, but first let me . . .”). Following anger, the patient will likely try to “bargain,” or make agreements that at least in the patient’s mind will postpone death for a short time.

Depression (“Okay, but I haven’t . . .”). As reality settles in, the patient may become silent, distant, sad, and despairing—usually about those he will leave behind and things left undone.

Acceptance (“Okay, I am not afraid.”). Finally, patients may appear to accept death, though not happy about it. At this stage, the family usually requires more support than the patient does.

Dealing with the Dying Patient, Family, and Bystanders

Although emergency care of the patient’s illness or injury is your priority, you have an obligation to help patients and others through the grieving process. Keep in mind that patients, families, and bystanders may be progressing through the stages at different rates. Whatever stage they are in, their needs include dignity, respect, sharing, communication, privacy, and control. To help reduce their emotional burden:

- Do everything possible to maintain the patient’s dignity. Avoid negative statements about the patient’s condition. An unresponsive patient may hear what you say and feel the fear in your words. Even if the patient is unresponsive, talk to him as if he is fully alert and explain the care you are providing.

- Show the greatest possible respect for the patient, especially when death is imminent. Families will be extra sensitive to how the dying relative is treated. Even attitudes and unspoken messages are perceived. Allow family members to stay with the patient during resuscitation efforts, explain what you are doing, and assure them that you are making every possible effort to help the patient. It is important for the family to know with certainty that you never simply “gave up.”

- Communicate. Help the patient become oriented to surroundings. Explain several times, if necessary, what has happened and where it has happened. Explain who you are and what you and others are planning to do. Assure the patient that you are doing everything possible and that you will see that the patient gets to a hospital as quickly as possible for further care. Without interrupting care for the patient, communicate the same message to the family. Explain any procedures you need to carry out. Give straightforward answers to questions. Report what you know to be true, but do not guess or make assumptions.

- Allow family members to express themselves. They should be able to scream, cry, or vent grief in a way that is not hazardous to you or others. This can help them progress through the stages of the grieving process. If they direct anger at you, remember not to take the attack personally. Be tolerant and avoid getting defensive.

- Listen empathetically. Many dying people want messages delivered to survivors. Take notes and assure the patient that you will do whatever you can to honor his requests. Then, follow through on your promise. If possible, you or a member of your team should stay with the family to listen to their concerns and answer their questions.

- Do not give false assurances, but let the patient know that everything that can be done to help will be done. Allow for some hope. Be honest but tactful. If the patient asks if he is dying, do not confirm it. Patients who do the most poorly are often the ones who feel hopeless. Instead, say something like “We are doing everything we can for you. We need you to help us by not giving up.”

- Use a gentle tone of voice with the patient and family. Explain the scope of the injury or problem, the procedures you are doing, and related information as kindly as you can in terms the family can understand.

- Take appropriate steps if the family wants to touch or hold the body after death. If family members want to touch or hold the body after death (and if local protocol allows), arrange for it. Do what you can to improve the appearance of the body. Clean vomitus, blood, or secretions from the face and hands. Elevate the head for a few minutes to allow fluids to drain. If the body is mutilated, warn the family first, and explain that you have covered the badly injured parts. If a possible crime is involved, do not clean the patient or remove any blood. Do not allow the family to enter the crime scene or to touch the body until permission is granted by law enforcement, coroner, or medical examiner. It is vital that all crime scene evidence is preserved.

- Do what you can to comfort the family. Offer help to family members who are at the scene. Even if death is imminent, arrange for them briefly to see and talk to the patient. This should not interrupt your emergency care or delay transport. Encourage the family to talk to an unresponsive patient. Explain that the patient may still hear and understand. If the patient is deceased and the family asks you to pray with them, do so if you feel comfortable about it. Stay with the family until the medical examiner or coroner arrives. Finally, if a family member asks to accompany the patient in the ambulance, make the arrangements if at all possible.
High-Stress Situations

Patients, families, and bystanders are not the only ones who experience extreme stress in an emergency situation. The EMT does too. Accepting and understanding that fact is the first step in learning how to handle it in healthy ways.

Stress is any change in the body’s internal balance. It occurs when external demands become greater than personal resources. Top sources of stress for the EMT include long hours, boredom between calls, working too much and too hard, getting little recognition, having to respond instantly, making life-and-death decisions, fearing serious errors, dealing with dying people and grieving survivors, and being responsible for someone’s life (Figure 2-1 ■).

Many emergency calls may be considered “routine” with a minimal level of stress. However, the nature of some calls may produce extreme levels of stress. Some of these situations include:

- Multiple-casualty incidents (MCIs) involving multiple patients at a single scene
- Abuse and neglect of infants, children, adults, and the elderly
- Emergencies involving infants and children
- Injury or death of a coworker
- Responding and providing emergency care to a relative or bystander
- Severe traumatic injuries such as amputations

Stress Reactions

There are three basic types of stress reactions that the EMT may experience as a result of a high-stress incident or from constant exposure to stressful situations. The types of stress reactions are:

- **Acute stress reaction.** An acute stress reaction results from exposure to a high-stress situation. You may note the reaction not only in the patient or bystanders, but also in you, your partner, or other emergency service personnel at the scene of the high-stress incident. Signs and symptoms typically occur immediately or shortly after the incident and may involve cognitive, physical, behavioral, or psychological functions. If the patient is experiencing what appears to be a medical emergency, such as chest pain or shortness of breath, it may be necessary to provide emergency care and seek further medical treatment. If it is you, your partner, or another emergency worker with signs or symptoms of a possible medical emergency, seek immediate medical treatment.

- **Delayed stress reaction.** Posttraumatic stress disorder (PTSD) is a typical delayed stress reaction that occurs from exposure to a high-stress situation; however, the signs and symptoms are not evident immediately. It may be days, months, or even years before the patient begins to experience the signs and symptoms of stress. Since a period of time typically passes before the onset of signs and symptoms, it may be difficult to relate the stress reaction to the particular past incident that caused the condition, and the patient may not understand why he is experiencing it. PTSD typically produces nightmares, irritability, insomnia, inability to think clearly or concentrate, flashbacks, increased interpersonal conflicts, and a decreased ability to relate to others. People suffering from PTSD may seek relief through drug or alcohol use. A person experiencing PTSD needs to seek help from a mental health professional.

- **Cumulative stress reaction.** As the name implies, cumulative stress reaction is a result of constant exposure to stressful situations that build over time. This is a common cause of burnout—a state of exhaustion and irritability. Initially, the signs and symptoms are not well recognized and may include an increase in anxiety and irritability. As the stress progresses, a state of emotional exhaustion may be reached and the condition may progress to more severe physical ailments. It can markedly decrease an EMS provider’s effectiveness in delivering emergency medical care. Some of the very best providers have had to leave the profession because of it. Many of the more severe signs and symptoms, listed next, are common in the cumulative stress reaction.

**Common Signs and Symptoms of Stress Reactions**

One of the best ways to prevent burnout is to recognize the warning signs of stress (Figure 2-2 ■). The earlier...
they are recognized, the easier they are to remedy. These warning signs include:

- Irritability with coworkers, family, and friends
- Inability to concentrate
- Difficulty sleeping and nightmares
- Anxiety
- Indecisiveness
- Guilt
- Loss of appetite
- Loss of sexual desire or interest
- Isolation
- Loss of interest in work

General categories of signs and symptoms also have been identified with stress. In addition to the warning signs just listed, these categories include:

- **Thinking.** Confusion, inability to make judgments or decisions, loss of motivation, chronic forgetfulness, loss of objectivity
- **Psychological.** Depression, excessive anger, negativity, hostility, defensiveness, mood swings, feelings of worthlessness
- **Physical.** Persistent exhaustion, headaches, gastrointestinal distress, dizziness, pounding heart
- **Behavioral.** Overeating, increased alcohol or drug use, grinding teeth, hyperactivity, lack of energy
- **Social.** Increased interpersonal conflicts, decreased ability to relate to patients as individuals

### Stress Management

Many EMTs expose themselves to overwhelming stress in the desire to help meet the needs of patients. They feel completely responsible for everything that happens on a run, even things that are clearly out of their control. Some are so involved that their self-image becomes based on job performance. As an EMT, you must maintain good physical, emotional, social, behavioral, and psychological health. To this end, it is critical that you not only recognize the signs and symptoms of stress reactions but that you also manage the stress immediately—before it progresses and interferes with your ability to function effectively, in and out of the field. The next section lists ways to help you cope.

### Make Lifestyle Changes

The following lifestyle changes can help you deal with stress:

- **Take a look at your diet.** Certain foods tend to increase the body’s stress response. So cut down on the amount of sugar, caffeine, and alcohol you consume. Increase the amount of lean protein you eat, limit your carbohydrates, and decrease your saturated fat intake (Figure 2-3a ■). While at work, eat frequently but in small amounts.

- **Exercise more often.** Exercise has all sorts of benefits (Figure 2-3b ■). One of the greatest is that it provides a physical release for the pent-up emotions that accompany many crises. Another is that it helps to prevent injury.

- **Learn to relax.** Practice relaxation techniques, such as taking a deep breath, holding it, and blowing out forcefully. Meditation and visual imagery techniques are also helpful ways to relax. You may also wish to try temporary diversions, such as watching a funny movie, reading a good book, or going to a concert with a friend. Cut loose a little bit.

- **Avoid self-medication.** Reaching for a bottle—whether it is filled with alcohol or with pills—does not help you cope with stress. In fact, it will increase stress. Your problems are still there when you come out of the stupor, and they will probably be worse because you did not act on them immediately.

### Keep Balance in Your Life

One way to keep a balance of work, recreation, family, health, and other interests is to assess your priorities.
Take a few minutes to list all your activities on paper. Write “1” beside your first priority, “2” beside your second, and so on. Then address those activities—all of them—in order of the priority you have assigned them.

You can also share your worries with someone else. Talking to someone you trust and respect can help relieve stress. It can also help you to discover alternatives that might have otherwise escaped you. A good confidante can listen empathetically and ask questions that will help you explore your ideas honestly. Talking with loved ones helps them understand what you may be going through. It also lets them feel included.

Still another way to help keep balance in your life is to accept the fact that you will occasionally make mistakes. Honestly admit to yourself that no person is right all of the time, and understand that a mistake does not reduce your value. You do not have to be perfect to do a good job.

Make Changes in Your Work Environment

The following changes in your work environment can help you manage job-related stress:

- **Frustrated desire to share.** You often find it too difficult to talk about what has happened during your shift. Your family and friends understand why, in a general way, but nevertheless feel frustrated in their desire to help and support you.

  Help family and friends understand the nature of your work and what you do for patients. Talk to them. Describe how you feel about what you do. Answer their questions. Explaining the safety precautions you and coworkers take every day can ease their anxieties.

  Encouraging them to join you in staying fit (daily exercise and planning healthy meals, for example) also can help alleviate their concerns when you cannot be with them. Always include time with them on your list of priorities.

- **Recognize the Response of Your Family and Friends**

  The support of your family and friends is essential in helping you manage stress. However, you may find that they, too, suffer from a certain amount of stress as a result of your job. You may find:

  - **Lack of understanding.** Families typically have little if any knowledge about prehospital emergency care.
  
  - **Fear of separation or of being ignored.** Long hours and demanding physical labor can take their toll and increase your family’s distress over your absences. Typically you may hear: “Your job is more important to you than your family!”
  
  - **Worry about on-call situations.** Stress at home may increase because your family may overemphasize or exaggerate the danger you face when you respond to emergency calls.
  
  - **Inability to plan.** Family and friends may not understand why you cannot leave your call area or have to leave an event early. Typically you may hear: “You’re not the only one on call. Let someone else go this time.”

  - **Follow a healthy diet.** (a)
  
  - **Aerobic exercise is an effective way to relieve stress.** (b)
  
  - **Develop a “buddy” system with a coworker.** Keep an eye on each other, and suggest when relaxation or a diversion is advisable. Try a relaxation technique whenever you find your effectiveness diminishing.
  
  - **Encourage and support your coworkers.** Make positive remarks, and resist the temptation to criticize or dwell on the negative.
  
  - **Periodically take a break to get some exercise—** do some type of aerobic exercise, such as taking a brisk walk, riding an exercise bike, walking or running on a treadmill, using an elliptical machine, or a similar activity.
  
  - **Request work shifts that allow you more time to relax** with your family and friends.
  
  - **Request a rotation of duty assignment** to a less busy area or an area with a different type of call volume. As an example, move from a station that deals primarily with calls involving crime and violence to a station that responds to more illnesses.
**Seek Professional Help**

You can also seek advice from mental health professionals, who can help you realize that your reactions are normal, mobilize your best coping strategies, and arm you with more effective ways to deal with stress in the future.

**Critical Incident Stress Management**

Emergency service personnel who suffer critical incident stress develop many of the signs and symptoms of burnout. They also may suffer from repeated mental images of the incident, fear of continuing in EMS work, and inability to function at the scene of subsequent emergencies. Critical incident stress management (CISM) is a process to deal with stress encountered by the EMT. It consists of two different approaches to stress management: critical incident stress debriefing and critical incident defusing.

A critical incident stress debriefing (CISD) is ideally held within 24 to 72 hours of a critical incident. During CISD, a team of peer counselors and mental health professionals help emergency service personnel work through seven phases. These phases are intended to allow the participants to review the facts of the event, share their feelings, identify signs and symptoms they are experiencing, sort through their feelings with the assistance of a mental health professional, receive suggestions for overcoming the stress, develop a plan of action for returning to the job, and be able to obtain follow-up assistance if lingering issues are present. CISD is not meant to assign blame. All information that is shared remains confidential.

CISD typically includes anyone involved in the incident—law enforcement personnel, firefighters, EMS personnel, communications personnel, and hospital emergency department personnel. In some cases, the debriefing may involve emergency service personnel family members, who are inevitably affected by the stress of the incident. In cases of multiple casualties, such as earthquakes, tornadoes, or severe hurricanes, a number of CISD meetings involving hundreds of people may need to be conducted.

Even if professional counselors are involved in sessions, CISD is not, in itself, professional counseling. Rather, it is a means to relieve stress.

Defusing is a version of CISD held within 1 to 4 hours following a critical incident. It is attended only by those most directly involved in the critical incident and lasts only 30 to 45 minutes. Less structured than a CISD meeting, defusing gives the smaller group of emergency service personnel an opportunity to vent their emotions and get information they may need before the larger group meets for CISD.

CISD has become controversial for many providers. The controversy stems from the need for scientific evidence that CISD truly assists emergency care personnel in resolving stress issues. It is important to keep current with the literature so that you may stay informed about the effectiveness of CISD. It is also important to recognize that a comprehensive critical stress management program involves more than CISD. Comprehensive critical incident stress management should include:

- Preincident stress education
- On-scene peer support
- One-on-one support
- Disaster support services
- Defusing
- CISD
- Follow-up services
- Spouse and family support
- Community outreach programs
- Other health and welfare programs

**SCENE SAFETY**

Keeping yourself safe at the scene of an illness or injury involves taking appropriate measures to protect yourself from infectious disease, following proper rescue procedures, and knowing how to handle violence, especially at a crime scene. It is also important to be an advocate for these protective measures—to help keep fellow emergency service personnel, as well as yourself, safe and well.

**Protecting Yourself from Disease**

**How Diseases Spread**

Diseases are caused by pathogens, which are microorganisms that are typically visible only through a microscope and may be found in the environment around you and also residing on or within the patient you are assessing and treating. The most common pathogens you will encounter are bacteria, viruses, fungi, protozoa, and helminths.

- **Bacteria** are microscopic single-celled organisms that have the capability of reproducing on their own within a host (patient’s body) that can provide a favorable environment and food supply. Common diseases produced by bacteria include sinus infection, ear infection, pneumonia (bacterial), strep throat, tuberculosis, and urinary tract infections. Bacterial infections typically respond to antibiotic treatment.

- **Viruses**, which are even smaller than bacteria, cannot grow on their own but require a host cell to reproduce. The virus invades a cell, reproduces, and then releases new virus particles that infect other cells. Those cells then produce more virus, spreading the infection throughout the body. Viruses are resistant to antibiotic treatment because they are located and unreachable within the host cell. Fortunately, most viruses are mild and self-limiting, such as the common cold or the flu. Conditions caused by viruses include acquired immune deficiency syndrome (AIDS) from the human immunodeficiency virus (HIV), hepatitis (A, B, and C), pneumonia (viral),
severe acute respiratory syndrome (SARS), chicken pox, and respiratory syncytial virus (RSV).

- **Fungi** are plantlike microorganisms that typically do not cause infection in a person with a normally functioning immune system. In a patient with a compromised immune system, fungi may cause diseases that would not be typically found, such as pneumonia in the HIV-infected person.

- **Protozoa** are single-celled organisms that are typically found in the soil and are able to move. Patients infected by protozoa often have a compromised immune system; however, some protozoa can cause infection in an uncompromised patient. The protozoa frequently enter the body through a fecal-oral route. Mosquitoes are carriers of protozoa that cause malaria. Some forms of gastroenteritis and vaginal infections are caused by protozoa in uncompromised immune systems.

- **Helminths** are parasitic worms, such as roundworms, flukes, and tapeworms, that cause infection. The helminth is typically introduced into the body by ingestion of worm eggs found in infected food or water or through the worm larvae invading through the skin. Hookworm, an example of a helminth infection, is a condition in which the parasitic worm attaches to the patient’s intestine, leading to blood loss and anemia.

Pathogens can spread in a number of ways, including by way of blood and other body fluids or through the air. Infectious diseases are contracted from a pathogen transmission but may not necessarily be communicable. For example, malaria is an infectious disease that is spread primarily through mosquitos (vector-borne) but cannot be transmitted through person-to-person contact. A communicable disease is one that spreads from person to person (Table 2-1). It can spread directly through blood-to-blood contact, contact with open wounds and exposed tissue (Figure 2-4 ■), and contact with the mucous membranes of the eyes and mouth. It can also spread indirectly by way of a contaminated object such as a needle. Airborne pathogens are spread by one person coughing, sneezing, or exhaling infected droplets that are then breathed into the respiratory tract of another person.

### Standard Precautions

U.S. Department of Occupational Safety and Health Administration (OSHA) guidelines require emergency care personnel to take precautions against disease transmitted by blood and other potentially infectious substances or body fluids. Also, employers share the responsibility with the employee to ensure that the necessary

control plan and providing training, certain immunizations, and the proper equipment for protection against disease transmission. The employee must complete the training and follow the procedures outlined in the exposure control plan.

The employer is also responsible for developing and enforcing a written policy to be used in the case of an exposure of an employee to an infectious substance such as blood or other body fluids. Needlesticks or direct contact with potentially infectious body fluids must be properly documented. Some policies require baseline infection testing of the exposed worker immediately with subsequent testing at designated intervals. Federal legislation has been enacted to allow for notification of EMS personnel who have come in contact with a patient who is infected with a communicable disease such as HIV, hepatitis B virus (HBV), or tuberculosis bacterium (TB) (Figure 2-5).

The following table outlines the steps that should be taken in the event of an exposure to an infectious disease such as TB (Tuberculosis) or HIV (AIDS virus) or HBV (Hepatitis B virus).

<table>

Protecting yourself from disease transmission through exposure to blood and other body fluids was formerly referred to as body substance isolation (BSI); it is more recently called **Standard Precautions**. The equipment utilized for Standard Precautions is referred to as **personal protective equipment (PPE)**. The following are guidelines for Standard Precautions.

**Hand Washing.** *Hand washing is the single most important way you can prevent the spread of infection* (Figure 2-6 ■). The spread of infection to you as the provider and from you, then passing it from patient to patient, can be reduced by hand washing. *Methicillin/oxacillin-resistant Staphylococcus aureus* (MRSA) and *C. difficile* colitis are two infections whose spread the EMT can reduce by simple hand washing. According to the U.S. Public Health Service, most contaminants can be removed from the skin with 10 to 15 seconds of vigorous lathering and scrubbing with plain soap. *Note: You should wash your hands even if you were wearing gloves.*

For maximum protection, begin by removing all jewelry from your hands and arms. If there was any chance that the jewelry was contaminated, also clean it with soap and water. Then proceed to vigorously lather and rub together all surfaces of your hands. Pay attention to creases, crevices, and the areas between your fingers. Use a brush to scrub under and around your fingernails. *(It is recommended that you keep your nails short and unpolished.)* If your hands are visibly soiled, spend more time washing them. Wash your wrists and forearms if they were exposed or possibly contaminated. Rinse thoroughly under a stream of running water. Dry well, using a disposable towel if you can.

**Alcohol-based hand sanitizer** can be used if you do not have access to soap and running water in the field. According to the Centers for Disease Control (CDC), use an alcohol-based hand sanitizer that contains at least 60 percent alcohol. Sanitizers don’t eliminate all of the germs; therefore, be sure to wash your hands thoroughly as soon as possible.

**Personal Protective Equipment.** Always use PPE as a barrier against infection. It will help to prevent your skin and mucous membranes from coming in contact with a patient’s blood and other body fluids. PPE includes eye protection, protective gloves, gowns, and masks (Figure 2-7 ■).

- **Eye protection.** Use eye shields to protect against blood and other body fluids splashing into your eyes. Several types are available (Figure 2-8 ■): clear plastic shields that cover the eyes or cover the whole face, protective eyewear (safety glasses) with side shields, and, if you wear prescription eyeglasses, there are removable side shields you can attach to your glasses. Form-fitting goggles also are available but are not required.

- **Protective gloves.** Wear high-quality vinyl, latex-free, or other synthetic gloves whenever you care for a patient. If a glove accidentally tears while in
use, remove it as soon as you can do so safely. Then wash your hands and replace the glove with a new one. Never reuse gloves. Put on a new pair of gloves between contacts with different patients to avoid exposing one patient to another’s infection. Also, use a proper technique for removing contaminated gloves so that you do not accidentally expose yourself to any blood or other body fluids contained on the gloves’ surface (EMT Skills 2-1). Upon glove removal, be sure to wash your hands thoroughly. In addition, wear a good pair of utility gloves when cleaning vehicles and equipment.

- **Gowns.** Wear a gown in any situation where there may be significant contact with blood or other body fluids, such as during childbirth. If possible, use a disposable gown. If at all possible, also change your uniform after caring for a patient in a large-splash situation.

- **Masks.** Wear a disposable surgical-type face mask to prevent blood or other body fluids from being splashed into your nose or mouth. You may also put a surgical mask on the patient if an airborne disease is suspected (Figure 2-9 ■). If you are treating a patient suspected of having tuberculosis, you need additional protection. Wear a high-efficiency particulate air (HEPA) respirator or an N-95 respirator (Figure 2-10 ■).

**Additional Guidelines.** The following guidelines should be observed as part of routine patient care:

- Whenever possible, use disposable equipment. Disinfect or sterilize nondisposable equipment according to local guidelines and protocols.

- Never reuse disposable equipment. Discard it after use with one patient. If you suspect that a patient may have an infectious disease, place used disposable equipment in a plastic bag clearly labeled as biohazardous or infectious waste. Then seal the bag. Equipment used with HIV, hepatitis B, or other infectious patients should be double-bagged.

- If your uniform gets soiled with body fluids, remove, bag, and label it. It should be washed in hot soapy water for at least 25 minutes. Take a hot shower yourself, and rinse thoroughly.

- After transferring care of a patient, gather all disposable equipment soiled by blood and other body fluids. Bag and seal it. Then label it as infectious waste (Figure 2-11 ■).

- Document in your logbook or on your flow sheet any contact with blood or other body fluids and any cleaning you have done as a result.

- Sponge, wipe, or wash noncritical items that do not ordinarily touch the patient or only touch intact skin.
derivative (PPD) tuberculin test to detect tuberculosis every year. This and the other immunizations listed here are recommended for active-duty EMTs:

- PPD tuberculin test (annually)
- Tetanus prophylaxis (every 10 years)
- Hepatitis B vaccine
- Influenza vaccine (annually)
- Polio immunization (if needed)
- Rubella (German measles) vaccine
- Measles vaccine (if needed)
- Mumps vaccine (if needed)
- Varicella vaccine (if needed)

Because some immunizations have been found to offer only partial protection, have your physician verify your immune status against rubella, measles, and mumps and obtain a hepatitis B titer. Although immunizations offer protection against many diseases, Standard Precautions must always be practiced, even by immunized EMTs.

**Reporting Exposure.** State and local laws vary regarding the reporting of exposure to blood and other body fluids, especially if a patient is known to be HIV positive or have hepatitis B or is known to be in a high-risk category for infection. In general, promptly report any suspected exposure to your supervisor, including date and time of the exposure, type of body fluid involved, the amount of fluid, and details of the exposure. Follow local protocol and your service’s exposure policies.

### Infectious Diseases of Concern to the EMT

#### Hepatitis B

Hepatitis B is one of several viruses that directly affect the liver. A serious disease that can last for months, hepatitis B can be contracted through blood and body fluids. A major source of the virus is the chronic carrier, who usually has no signs or symptoms and is often unaware of being ill. These people can transmit the disease at any time.

The following are signs and symptoms of the hepatitis B virus:

- Fatigue
- Nausea and loss of appetite
- Abdominal pain
- Headache
- Fever
- Yellowish color of skin and whites of eyes (jaundice)
- Dark urine

Remember: Hepatitis B infection may not cause symptoms. You can be unaware of infection and still pass it on to others. Protective procedure recommendations include the following:

- Wear disposable protective gloves whenever you care for patients to prevent contact with blood and other
body fluids. Make sure you have bandaged all cuts, lesions, scratches, hangnails, and any other open wound on your hands.

- After removing gloves, wash your hands, wrists, and forearms thoroughly with hot, soapy water and rinse well.
- Get vaccinated against hepatitis B before beginning EMS field work. These vaccines are offered by employers when employees have the potential to come in contact with blood and body fluids.
- Double-bag and seal all soiled refuse. Dispose of it according to local protocol.
- Clean and disinfect or sterilize all nondisposable equipment. Launder your soiled clothing in hot, soapy water and bleach.

If you suspect you have been exposed to hepatitis B, report the incident to your supervisor and follow your service’s exposure policy. Care may include an injection of HBIG (hepatitis B immunoglobulin) immediately and again within a month if not previously vaccinated. You may also receive a vaccination, if you have not already had one.

### Hepatitis C

Hepatitis C virus (HCV) infection has become the most common bloodborne infection in the United States. Fortunately, the risk of transmission through occupational exposure is relatively low since it requires introduction through the skin by needlestick. Transmission via the mucous membrane is rare. Testing of emergency personnel is recommended after exposure has occurred. Approximately 80 percent of patients with HCV have no signs or symptoms. Those who are symptomatic typically present with the following:

- Jaundice (yellow color to skin and eyes)
- Fatigue
- Abdominal pain (may be located in right upper quadrant)
- Nausea
- Dark urine
- Loss of appetite

Unlike with hepatitis B, there is no vaccination to prevent hepatitis C infection. It is extremely important that you take Standard Precautions when dealing with exposure to body fluids, especially blood. Also be careful to avoid any sharps or needles with infected blood since this is the most significant route of HCV transmission for EMS personnel.

### Tuberculosis

Tuberculosis almost vanished once, but it has made a dramatic comeback. In fact, researchers are worried because new drug-resistant strains are developing. The pathogen that causes tuberculosis is found in the lungs and other tissues of the infected patient. You can be infected by droplets from the cough of a patient and from the patient’s infected sputum.

The main signs and symptoms of tuberculosis are as follows:

- Fever
- Cough (often coughing up blood)
- Night sweats
- Weight loss

OSHA has adopted protective procedure standards for rescuers. The standards include the use of special HEPA or N-95 respirators. Recommendations include the following:

- Wear disposable protective gloves to avoid contact with infected sputum or mucus.
- Wear a HEPA or N-95 (respirator) mask to avoid breathing infected droplets.
- Perform artificial ventilation with OSHA-approved equipment.
- After you remove your gloves, wash hands thoroughly with hot soapy water and rinse well.
- Disinfect all nondisposable equipment that was contaminated by the patient’s body fluids with a hospital-grade disinfectant with a tuberculocidal agent. See that all linens and clothing are laundered in hot soapy water and bleach.

### Human Immunodeficiency Virus (HIV)/Acquired Immune Deficiency Syndrome (AIDS)

Fortunately, AIDS is not spread through casual contact. It cannot be transmitted by coughing, sneezing, sharing eating utensils, linens, skin contact, or such indirect exposures. It is more difficult to contract HIV (human immunodeficiency virus, the virus that causes AIDS) through occupational exposure than it is to contract the virus that causes hepatitis B. The identified modes of transmission include the following:

- Sexual contact involving the exchange of semen, blood, or through contact with vaginal or cervical secretions
- Infected needles
- Infected blood or blood products
- Mother–child transmission, which occurs when an infected mother passes the virus to her child, sometimes as early as the 12th week of gestation
- Contact with infected blood or secretions through mucous membranes or open skin

Simply stated, AIDS is a syndrome of medical problems caused by HIV, a virus that destroys the body’s ability to fight infections. Many patients infected with HIV do not exhibit signs or symptoms and do not know they are infected. AIDS patients become infected with what are called opportunistic infections (infections that take
advantage of the “opportunity” provided by the body’s lack of ability to fight them). These infections are caused by viruses, bacteria, parasites, and fungi. They are serious illnesses that either do not occur or occur only in milder forms among people with healthy immune systems.

AIDS can involve many organs and systems of the body. This results in a countless array of signs and symptoms. The most common include the following:

- Persistent, low-grade fever
- Night sweats
- Swollen lymph glands
- Loss of appetite
- Nausea
- Persistent diarrhea
- Headache
- Sore throat
- Fatigue
- Weight loss
- Shortness of breath
- Mental status changes
- Muscle and joint aches
- Rash
- Various opportunistic infections

Remember—not everyone who is infected by HIV has yet developed, or even will develop, AIDS. However, people who carry HIV are still capable of spreading the infection to others, even if they have no signs or symptoms. Follow Standard Precautions at all times. They can significantly reduce your risk of becoming infected with HIV.

**Severe Acute Respiratory Syndrome (SARS)**

Severe acute respiratory syndrome (SARS) is caused by a respiratory virus that was found in Asia in 2003. SARS cases have been identified worldwide, including in the United States and Canada. The virus is thought to be transmitted by close person-to-person contact by respiratory droplets produced by the infected person who coughs or sneezes. Close contact is generally defined as within 3 feet of the infected person. The respiratory droplets are then deposited on the mucous membranes of the mouth, nose, or eyes of the noninfected person. Also, the respiratory droplets may be deposited on an object that is touched by a noninfected person who then touches his eyes, inside his mouth, or his nose and subsequently becomes infected.

The following are signs and symptoms of SARS:

- A high fever of usually greater than 100°F (38°C)
- Headache and body ache
- General feeling of discomfort
- Respiratory symptoms
- Diarrhea
- Dry cough

Most patients with SARS will develop pneumonia. The patient may then present with more severe signs of respiratory distress.

The best protection for the EMT if SARS is suspected is to wear a surgical mask to avoid inhaling respiratory droplets, eye protection to avoid droplets entering the mucosa of the eyes, and gloves. Also place a surgical mask on the patient. When dealing with the patient or equipment used on the patient, do not touch your eyes, nose, or mouth with your gloved hands. Be sure to immediately remove the gloves after the patient exposure and wash your hands thoroughly. If you think you have been exposed, contact the person who manages infectious disease exposure at your EMS agency. Be alert for signs of fever and respiratory symptoms for 10 days after the exposure.

**West Nile Virus**

West Nile virus (WNV) is transmitted through the bite of an infected mosquito. Most mosquitoes are infected by feeding off an infected bird. Approximately 80 percent of the people infected with WNV will not show any signs or symptoms. However, some patients will present with severe to mild signs and symptoms. These include the following:

**Severe Signs and Symptoms**

- High fever
- Headache and stiff neck
- Confusion and disorientation to coma
- Seizures
- Muscle weakness
- Numbness
- Paralysis
- Vision loss

**Mild Signs and Symptoms**

- Fever
- Headache and body ache
- Nausea and vomiting
- Skin rash to chest, stomach, and back
- Soreness to neck from swollen lymph glands

The signs and symptoms of the severe cases may last for several weeks. Some of the signs and symptoms may be permanent. In mild cases, the signs and symptoms can last for only a few days to several weeks.

Standard Precautions will protect you from the virus. You are much more likely to contract the virus from a mosquito bite than through an occupational exposure from coming in contact with a patient who has the West Nile virus.

**Multidrug-Resistant Organisms**

Multidrug-resistant organisms are pathogens that have adapted to and developed the ability to resist standard antimicrobial drugs. As an EMT, you will likely come in contact with these pathogens while transporting patients from hospitals, especially intensive care units and burn units, long-term care facilities, nursing homes, and other
Protecting Yourself from Accidental and Work-Related Injury

As an EMT you must constantly be aware of the risk of potential injury associated with even the everyday aspects of the profession. Prevention of work-related injuries is addressed in many chapters throughout the book. Prevention strategies include the use of vehicle restraint systems, safe lifting and moving techniques, getting adequate sleep, physical fitness, proper nutrition, and practicing proper Standard Precautions against disease transmission.

You must also protect yourself during rescue operations involving hazardous materials, potentially life-threatening rescues, violence, and biological and chemical weapons of mass destruction. It is imperative that you not fall victim to the same hazards that affect your patients.

Hazardous Materials

Whenever you are called to a scene involving possible hazardous materials, use binoculars to try to identify the materials as hazardous before approaching. Look for signs or placards and compare them to those listed in the Emergency Response Guidebook, published by the U.S. Department of Transportation (Figures 2-13 and 2-14). A copy of the handbook should be in every emergency vehicle.

Rescuers trained in managing hazardous materials wear protective clothing at a hazardous materials emergency, including self-contained breathing apparatus and “hazmat” suits (Figures 2-15 and 2-16). Whenever possible, a specialized hazardous materials team should be called to control the scene before you enter. EMTs should provide emergency care only after the scene is safe, contamination is limited, and patient decontamination has been accomplished. See Chapter 44 “Hazardous Materials,” for detailed discussion.
Rescue Situations

The following rescue situations involve potential threat to the life of both patients and emergency service personnel:

- Downed power lines or other potential for electrocution (Figure 2-17 ■)
- Fire or threat of fire (including gasoline or chemical spills)
- Explosion or threat of explosion
- Hazardous materials
- Possible structural collapse
- Low oxygen levels in confined spaces
- Trenches that are not properly secured
- Biological, nuclear, and chemical weapons

Generally, you should call for assistance from specialized teams—from the power company or fire department, for example—before attempting rescue or patient treatment in a situation involving a life-threatening danger. If complex or extensive rescue is involved, also call for specialized rescue teams. Once a scene is controlled, follow local protocol in wearing the necessary personal protective equipment, such as turnout gear, puncture-proof gloves, helmet, and protective eyewear (Figure 2-18 ■).
Plenty of rescues take place outdoors in the dark and in bad weather. If the rescue is being performed on a roadway, an essential for every rescuer is an ANSI/ISEA 107-2004 Class 2 or Class 3 approved high-visibility vest or 207-2006 public safety vest (PSV), as discussed in the next section. Depending on the situation, you might consider rubber or waterproof boots and slip-resistant waterproof gloves in wet weather. In cold weather, wear gloves, a warm hat, and long underwear, as well as several layers of clothing on your torso. In accidents involving grain, cement, or similar materials, wear a dust respirator. If there is any risk of falling debris, wear an impact-resistant protective helmet with reflective tape and a strap under the chin.

It is vital to your safety that you follow your system’s protocols and policies on personal protection. A good rule is to be sure that you wear at least the protective equipment that others on the scene are required to wear. For example, if you are responding to a call at a factory and all the employees are required to wear a helmet while in the plant, the minimum protection you should wear is a helmet.

High-Visibility Vest. A recently approved federal law requires all EMTs and other rescue personnel responding to accidents or other emergencies on or near a roadway to wear approved high-visibility apparel in an attempt to reduce the incidence of injury to emergency responders.

The American National Standards Institute (ANSI) and International Safety Equipment Association (ISEA) created the standard ANSI/ISEA 107-2004, American National Standard for High-Visibility Safety Apparel and Headwear. Three classes of garments were established:

- **Class 1**—designed for workers in parking lots and other areas with traffic flow moving at less than 25 mph
- **Class 2**—designed for personnel whose attention is diverted from traffic or where the traffic flow is moving at 25 mph or greater
- **Class 3**—designed for personnel whose work greatly diverts their attention away from the roadway and where they are at serious risk from hazards created by moving vehicles

The ANSI/ISEA 207-2006 American National Standard for High-Visibility Public Safety Vests (PSV) was approved to increase the visibility of emergency personnel on the roadway and to reduce the incidence of roadway hazards. The newer standard made significant changes to standard class garments to accommodate the public safety responder. The PSV has the same retro-reflective material as the Class 2 vest and nearly the same amount of fluorescent material. The PSV has breakaway features, specific vest dimensions to allow for fit over turnout gear, and color-specific markings to allow for differentiation between law enforcement, fire, and EMS personnel.

Currently, the Code of Federal Regulations requires all emergency personnel who are exposed to traffic within the right-of-way of a highway that receives federal funding to wear high-visibility safety apparel that meets the Class 2 or 3 standards of ANSI/ISEA 107-2004 or the Public Safety Vest standard ANSI/ISEA 207-2006. Additional information to protect emergency medical personnel while working on or near a roadway is found in Chapter 42, “Ambulance Operations and Air Medical Response.”

### Violence and Crime

You may face violence without warning—from a patient, bystander, family member, perpetrator of a crime, or behavioral emergency patient—during any patient rescue or treatment situation. Generally, if you suspect potential violence, you should call law enforcement before you enter the scene, especially if the perpetrator of a crime is or may still be present. Do not enter the scene to render patient care until it has been adequately controlled by law enforcement and until those with weapons (such as guns or knives) have been removed from the scene. Typical emergencies in which you should call law enforcement include domestic...
disputes, patients under the influence of drugs or alcohol who appear to be agitated or hostile, street or gang fights, bar fights, potential suicide, scenes with angry family members or angry bystanders, behavioral emergencies with hostile action or threats, and any type of crime scene.

Regardless of where you work, you may want to consider using body armor, sometimes called a “bullet-proof vest.” Many metropolitan area EMS agencies issue body armor or provide some other means for personnel to be protected.

If you need to treat patients at a crime scene, take specific precautions to preserve the chain of evidence needed for investigation and prosecution. A general rule is to avoid disturbing the scene unless absolutely necessary for medical care. More specific details on crime scene behavior are listed in Chapter 3, “Medical, Legal, and Ethical Issues.”

## WELLNESS PRINCIPLES

Remaining well is a fundamental aspect that allows you to perform your responsibilities as an EMT to the best of your ability. Wellness does not simply imply the lack of illness; it involves physical, intellectual, emotional, social, environmental, and spiritual dimensions. An imbalance in any of these dimensions could lead to a state of poor health. The following sections focus on the physical and mental components of wellness.

### Physical Well-Being

Physical well-being focuses on the body and the ability to perform the physical demands of being an EMT. It includes physical fitness, adequate sleep, disease prevention, and injury prevention. Methods to reduce your incidence of acquiring an infectious disease and techniques to prevent injury from safety hazards have been discussed earlier in the chapter. Additional information regarding the prevention of injury associated with proper lifting and moving techniques will be discussed in Chapter 6, “Lifting and Moving Patients.”

### Physical Fitness

The core components to remaining physically fit and able to perform your job as an EMT are cardiovascular endurance, muscle strength, muscle endurance, muscle flexibility, and body composition.

**Cardiovascular Endurance.** Cardiovascular endurance is gained through aerobic exercise that is geared toward improving the ability of the heart, lungs, and vessels to supply the muscles and organs with oxygen and other nutrients during prolonged periods of work. Walking, jogging, swimming, and using an elliptical or step machine can all help to strengthen the cardiovascular system. To obtain the benefits of cardiovascular exercise, it is necessary to reach and maintain your target heart rate for a period of time, often 30 to 40 minutes at least three days a week. Your target heart rate can be calculated by the following procedure:

1. Measure your resting heart rate.
2. Subtract your age from 220, which provides your estimated maximum heart rate.
3. Subtract your resting heart rate from your maximum heart rate, and then multiply that figure by 70% (0.70).
4. Add the final calculated number from step 3 to your resting heart rate.

The following is an example of calculating a target heart rate by this formula:

1. Resting heart rate is 62 beats per minute (bpm) for a 28-year-old.
2. Total estimated maximum heart rate is 192 bpm (220 – 28 = 192).
3. Total estimated maximum heart rate minus the resting heart rate is 130 bpm (192 – 62 = 130 bpm) multiplied by 70% = 91 bpm (130 × 0.70 = 91 bpm).
4. Target heart rate as calculated by adding the resting heart rate to the calculated figure in step 3 equals 153 bpm (91 + 62 = 153 bpm).

**Muscle Strength.** Muscle strength is defined as the amount of force a muscle can produce through a single contraction. It is tested by the amount of weight that can be lifted. The primary way to build muscle strength is through weight lifting or other types of resistance exercises. Lifting heavy objects is a crucial and repetitive part of an EMT’s job, including lifting patients and equipment.

**Muscle Endurance.** Muscle endurance is defined as the ability of the muscle to function repeatedly without unwarranted fatigue. Improvement in muscle endurance is achieved by forcing the muscles to lift a greater weight than the muscle is used to. This, again, is achieved through weight training. Muscle endurance is necessary to be able to carry patients and equipment for long periods of time, such as from a bedroom to the ambulance.

**Muscle Flexibility.** Muscle flexibility allows you to move your joints through the full range of motion. This is achieved primarily through stretching. Muscle flexibility is key to lifting and moving patients and equipment properly. Without adequate flexibility, you are prone to muscle and joint injury.

**Body Composition.** Body composition is evaluated primarily by the ratio of body fat to total weight.
A lower ratio of body fat is associated with a healthier individual. A higher ratio of body fat places the EMT at risk for chronic conditions such as heart disease, hypertension, and diabetes. Proper nutrition and exercise will help to reduce and/or maintain a proper ratio of body fat.

**Adequate Sleep**

EMS work is performed 24 hours a day, 7 days a week. When you work a shift that falls within a different span of the day than you are accustomed to being awake and alert, it interrupts your body’s natural timing system, referred to as circadian rhythms. Interfering with your body’s circadian rhythms makes you prone to difficulty with physical coordination, thought processes, and social functions.

One of the keys to maintaining as near normal function as possible is getting an adequate amount of sleep. Lack of sleep (sleep deprivation) puts you at risk for accidents and injury. It also puts your patients at risk of improper care resulting from your inability to function at the necessary mental and physical level. Individuals require a minimum of 8 to 10 hours of sleep each day. Studies have shown that a lack of regular sleep contributes to chronic diseases, such as heart disease, weight gain, and poor mental function. Methods to improve the quality and increase the number of hours of sleep include the following:

- Select an environment that mimics nighttime, such as one that is cool and dark.
- Select a regular time to sleep when a block of sleep can be achieved uninterrupted.
- Prepare yourself for sleep by not eating a heavy meal, drinking caffeine, or exercising immediately before your sleep time.
- Reduce interruptions by turning off the phone ringer, shutting off pagers, turning cell phones to the silent mode, and posting a sign on your door indicating that you are sleeping.

**Smoking Cessation**

Smoking contributes dramatically to an unhealthy lifestyle. As an EMS professional, you are part of the public health system. One of your responsibilities is to promote a healthy lifestyle in the public to reduce the incidence of disease, illness, and injury. By smoking, you are violating this responsibility and increasing your own risk of cardiovascular and pulmonary disease, and cancer. There are a number of strategies available to quit smoking. By doing so, you will not only improve your public image but also greatly improve your health.

**Alcohol- and Drug-Related Issues**

Some EMS providers resort to the use of alcohol or drugs, prescription or illegal, in an attempt to reduce the mental and physical stress associated with the job. Overindulgence in alcohol to reduce or relieve stress is a practice that must be avoided. It has consequences for your health and mental function, and it does not get rid of the stress. Similarly, the use of medications or illegal drugs to cope with stress is a grave warning sign. If you or a fellow EMT is relying on drugs or alcohol, it is necessary to seek professional assistance. Many EMS agencies have employee assistance programs that are extremely beneficial in situations like these.

**Mental Well-Being**

Stress associated with EMS can easily affect your mental well-being. Over time, this can lead to the development of chronic physical illness as well as emotional issues. Individuals who are close to you and who are not involved in EMS may not understand the stresses of the job and what you are experiencing. This can contribute to difficulty in relationships and an imbalance in your personal life. It is important to talk to family members or those you are close to and explain how you are feeling. They may not completely understand; however, it is a step toward helping them understand. Exercise, relaxation, and engaging in something you enjoy, such as fishing or hiking, are great ways to reduce stress and improve your mental well-being.

If these methods are not enough to help you achieve a feeling of mental well-being, look into any employee assistance programs your agency may provide or seek out other sources of help, such as professional counseling.
Follow a safe technique for removal of gloves. Use only contaminated glove surfaces to touch other contaminated glove surfaces, and use clean inside glove surfaces to touch other clean inside glove surfaces. Do not touch a contaminated surface with your bare hand or fingers.

Use a gloved finger to pull a cuff out and down on the other glove. Do not touch the inside of the glove.

Without touching the inside of the glove, continue pulling it downward.

Pull until the glove is inside out and off all but the tips of the fingers and thumb.
SUMMARY
As an EMT, you will be faced with death and dying on a regular basis. It is likely that what you will experience in a short while most people will not experience in a lifetime. Some patients who are terminally ill will go through certain stages related to death and dying. Family members may go through the same stages but at different times. Be prepared to deal with these patients, their families, and their emotions.

Stress is inherent in emergency medical services and may have significant physical, emotional, psychological, and social impacts on your life. Be prepared to recognize the warning signs and symptoms of stress. Stress reactions may be acute, delayed, or cumulative. Once you have recognized stress, use effective methods to diminish or eliminate it.

One of the most important aspects of scene safety is protecting yourself against any hazards. This includes taking the necessary Standard Precautions against infectious disease. If responding to a scene that involves specialized rescue, such as for hazardous materials or swift water, do not attempt any type of rescue yourself unless you have received the necessary specialized training and have the proper equipment. Responding to scenes that involve violence and crime may present certain risks. Be sure to have the proper resources dispatched to secure the scene.

Case Study Follow-up
Scene Size-up
You have been dispatched to the scene of a domestic dispute. You learn from the police that the husband is an unemployed alcoholic who is going through a “detox” program. He is holding his wife and two daughters hostage. An officer is already down, and a special tactics team is working to bring the situation under control.

Two hours later you are still not permitted to approach. The husband has released the two children and they are transported by another EMS unit. Suddenly there is a single gunshot. The husband appears at the front door, shooting randomly. The special tactics team returns fire. The man falls to the ground.

Patient Assessment
After the police secure the scene, you and your partner approach with Standard Precautions. Primary assessment shows that the downed police officer is dead, having received multiple gunshot wounds to the head and neck. The gunman is also dead, with multiple gunshot wounds to the head and chest. The wife inside the house is dead, shot once through the head. You and your partner return to the ambulance and notify dispatch that there will be no additional transports. The incident commander releases you and your partner from the scene.

Critical Incident Follow-up
During the drive back to the station, your partner is very quiet and tense. At the station, you try to get him to discuss the call. He responds angrily and tells you he is going to quit EMS. You both summon your supervisor, who recognizes the signs of acute stress reaction. The supervisor meets with the EMT and encourages him to contact the employee assistance program. He arranges to meet with a mental health professional to discuss the call. He returns to his next shift relaxed and confident that he can perform competently.

IN REVIEW
5. Identify some of the negative feelings families of EMTs may have in response to the job. Describe some of the ways you can help.
6. Describe the safety precautions an EMT can take to prevent the spread of infectious disease.
7. Discuss the responsibilities employers have, under OSHA guidelines, to protect emergency care personnel from transmission of infectious diseases.
8. Discuss the responsibilities emergency care employees have, under OSHA guidelines, for their own protection against transmission of infectious diseases.

9. List the personal protective equipment necessary for hazardous materials situations, rescue operations, and scenes of violence or crime.

10. List steps to prevent work-related injuries.

11. List common infectious diseases the EMT may encounter in the prehospital setting.

12. List strategies that contribute to physical and mental well-being.

CRITICAL THINKING

You are dispatched to the scene for a 3-year-old female child who was shot in the chest. As you arrive on the scene, you note blood covering the front porch and sidewalk.

1. What would you do to ensure scene safety?

2. What other resources should be requested?

3. Why is this a potential high-stress situation?

4. What can be done to reduce your stress associated with the call?
3-1. Define key terms introduced in this chapter.
3-2. Differentiate between the concepts of scope of practice and standard of care.
3-3. Given a scenario, determine whether you would have a duty to act.
3-4. Explain your duties with respect to patients, your partner, yourself, and your equipment.
3-5. Describe the intent of Good Samaritan laws.
3-6. Explain each of the following legal protections for EMTs:
   a. Sovereign immunity
   b. Statutes of limitations
   c. Contributory negligence of the patient
3-7. Explain the EMT's legal obligations with respect to medical direction.
3-8. Differentiate between the concepts of ethics and morals.
3-9. Describe the ethical responsibilities of EMTs.
3-10. Given a scenario presenting an ethical dilemma, discuss the consequences of various decisions and actions.
3-11. Explain each of the following types of consent:
   a. Informed consent
   b. Express consent
   c.IMPLIED consent
   d. Consent to treat minors
   e. Involuntary consent
3-12. Compare and contrast the typical provisions and prehospital applications of each of the following types of advance directives:
   a. Do not resuscitate order
   b. Living will
   c. Durable power of attorney
   d. Physician orders for life-sustaining treatment
3-13. Given a scenario in which a patient has an advance directive, determine the appropriate action to be taken.
3-14. Given a scenario in which a patient refuses care, discuss the actions you should take.
3-15. Differentiate between criminal and civil liability.
3-16. Explain the concept of negligence.
3-17. Give examples of ways you can avoid each of the following tort claims:
   a. Abandonment
   b. Assault
   c. Battery
   d. False imprisonment/kidnapping
   e. Defamation
3-18. Explain patients’ rights and your legal and ethical responsibilities concerning confidentiality and privacy.
3-19. Describe COBRA and EMTALA provisions as they apply to EMS.
3-20. Give examples of ways you can protect yourself legally in transport and transfer situations.
3-21. Describe special considerations for patients who are potential organ donors.
3-22. Identify presumptive signs of death.
3-23. Identify situations in which law enforcement or the medical examiner’s/coronor’s office should be contacted.
3-24. Discuss special considerations in responding to potential crime scenes.
3-25. Describe situations in which the EMT may be mandated to make a report, such as suspected abuse, crimes, and infectious diseases.
INTRODUCTION

Should you stop to treat an accident victim when you are off duty? May you treat a child when the parents are not present to give consent? Should you withhold cardiopulmonary resuscitation (CPR) if the patient’s family asks you to? You will often need to act on medical, legal, and ethical issues such as these during your career as an EMT.

At times you may wonder if you can provide emergency care at all without being sued! You are unlikely to be sued successfully if you provide and carefully document care within your scope of practice and local protocols, with knowledge of such issues as patient consent and duty to act.

THE SCOPE OF PRACTICE

Prehospital emergency care has changed significantly since its early days. One improvement has been in the quality of training that emergency medical personnel receive today. The public and the health care profession have come to expect a competent EMT who understands and accepts the legal and ethical responsibilities to the patient, to the medical director, and to the public.

Case Study

The Dispatch
EMS Unit 105—proceed to 733 East Third Street—you have an elderly male at that location with abdominal pain—time out 1430 hours.

Upon Arrival
An elderly woman, who tells you she is Mrs. Schuman, meets you and your partner on the front porch of the home. She is wearing only a nightgown, and the temperature is only 38°F. She says, “It’s my husband. Something is wrong. I just can’t handle him anymore.”

You quickly usher Mrs. Schuman inside while you scan the scene for hazards. As soon as you enter you notice that the house is in shambles. The rooms are so cluttered that you and your partner can barely pass through. Mrs. Schuman leads you to the bedroom, where you find the patient lying on the bed. Mr. Schuman’s eyes are open, and he’s moaning softly. His bed sheets and undergarments are stained with dried urine. The odor is very strong, and the temperature inside the room is very cold.

How would you proceed with this case?
During this chapter, you will learn about special legal and ethical considerations that have an impact on the medical care you administer to your patients. Later, we will return to the case and put in context some of the information you learned.

Legal Duties

Typically, state laws identify the EMT’s scope of practice, or the actions and care that EMTs are legally allowed to perform by the state in which they are providing emergency medical care. Scope of practice also identifies which activities would be deemed illegal if performed without licensure or certification and establishes boundaries among professionals. For example, providing oxygen under the appropriate circumstances is within the EMT’s scope of practice. However, suturing a laceration is not and is therefore illegal—even if the EMT may actually know how to perform the skill.
Among the sources commonly used to define the EMT’s scope of practice are the National Highway Traffic Safety Administration’s National EMS Scope of Practice Model and the National EMS Education Standards, which reflect minimum training standards applied throughout the United States, as well as state laws, regulations, and policies. The scope of practice is not a practice guideline or protocol and does not define the standard of care. It is purely a definition of what actions can legally be performed by the EMT.

The standard of care would be defined as the care that is expected to be provided by an EMT with similar training when managing a patient in a similar situation. The concept of “the reasonable person standard” is applied. That is, what would a reasonably prudent EMT with similar training do in the same situation? Also, standard of care asks whether the EMT provided the care properly. Thus, standard of care deals with two principles: (1) Did the EMT provide the right assessment and emergency care for the patient? and (2) Did the EMT perform the assessment and emergency care properly?

The scope of practice asks: Was the EMT allowed by law to do what he did? Falling below the standard of care would constitute negligence. The following sources may be used to define the standard of care:

- Recognized and accepted EMT textbooks
- The care that would be expected by other EMTs in the community or region
- Local and state protocols
- National Highway Traffic Safety Administration’s National EMS Education Standards
- The EMS system’s operating policies and procedures

Duty to Act

The concept known as duty to act refers to your legal obligation to provide service, whether you think the patient needs an ambulance or not. Legally, while you are on duty you are obligated to care for a patient who requires and consents to it, rendering the necessary emergency care to the best of your ability and training. If you are off duty and not functioning in an EMS capacity, however, in most states you have no more legal obligation to act than any other citizen. While off duty in these states, you could legally do any of the following:

- Stop and help the accident victim at the scene.
- Pass the scene and call for help. 
- Pass the scene and make no attempt to call for help.

Note, however, that some states do require EMTs to stop and render aid even when off duty.

Whether or not your state requires it, if you are off duty from your paid or volunteer service and publicly respond to a page for assistance at an emergency call, or if you come across a scene and decide to stop to provide emergency care, you will create a duty to act, even though you are off duty. The reason for this assumed duty to act is that others may not respond because they feel that your response has covered the call adequately and no other assistance is needed. If you begin emergency care and then decide to leave the scene, the patient could be placed in a situation that may be worse than if you had not responded at all. Once you do stop to help, thus creating the duty to act, you assume certain legal responsibilities. For example, once you have begun to provide care, you cannot leave until someone with the appropriate expertise—typically defined as one with an equal or higher level of training—takes over care. You are also legally responsible for any of the patient’s personal property that you pick up.

One of the most important aspects of duty to your patient involves respecting the rights of the patient. It is your responsibility to serve as the patient’s advocate and to protect and honor his rights. Part of that protection includes maintaining the privacy and confidentiality of the patient’s medical status, history, and records. You are there to lessen the patient’s suffering. You must also provide complete and competent care for your patient. This involves not only providing care for the physical injuries and illness, but also meeting the emotional needs of the patient. You must also do no further harm.

Your duty goes beyond accepting the responsibility to respond and provide emergency care to a patient. You also have a duty to self, a duty to your partner, and a duty to take responsibility for your equipment.

Your duty to self requires that you obtain the necessary credentials to practice as an EMT, that you maintain your skills to a level of proficiency, that you maintain your mental health, and that you remain physically able to perform the duties of the job.

Your duty to your partner involves ensuring that he is physically and mentally fit to provide emergency medical care and other responsibilities of the job. If your partner reports for work under the influence of alcohol or drugs, you have a duty to report the situation to your supervisor. In the end, it protects you and protects the public.

Your duty regarding your equipment is vital. It is your legal responsibility as an EMT to ensure that all of your equipment is in proper working order. This is done at the beginning of each shift. If a piece of equipment malfunctions because of improper maintenance, or if you don’t have a necessary piece of equipment to treat a patient, you are negligent in providing care to the patient.

Good Samaritan Laws

The first Good Samaritan law was enacted in 1959 in California specifically to protect from liability “persons licensed (such as a physician or surgeon) who in good faith render emergency care at the scene of the emergency . . . for civil damages as a result of any acts or omissions.” Many states have immunity laws of their own, some of which specifically cover prehospital emergency care providers.
Generally, a Good Samaritan law protects a person who is not being paid for his services from liability for acts performed in good faith unless those acts constitute gross negligence. Therefore, the person suing must prove that the care provided was markedly below the standard of care and, in some cases, with willful or wanton intent to harm the patient.

Most states have specific laws authorizing EMTs to perform prehospital emergency medical procedures without a medical license. Most states also provide some form of immunity to nurses, physicians, supervisors, and other personnel who give directions to EMTs by cell phone, telephone, or radio. The laws governing private and public providers vary. Be sure to learn your local laws.

A Good Samaritan law does not prevent you from being sued, although it may provide you some protection against losing the lawsuit if you have performed according to the standard of care for an EMT. So while you are on duty or assisting off duty, your best defense to lawsuits is prevention. Always render care to the best of your ability, always work within your scope of practice and within the standard of care, always behave in a professional manner, and ensure that you are covered by adequate liability insurance. If you keep your patients’ best interests in mind when rendering care, you will seldom, if ever, go wrong.

Other Legal Protections

Another type of immunity afforded to public or government emergency medical services is sovereign immunity. Sovereign immunity, also known as governmental immunity, prevents persons treated by governmental operated EMS systems from suing the government for civil liability. Since private EMS companies are not government agencies, they are not protected under sovereign immunity.

Each state has determined an appropriate statute of limitations relative to negligence claims. This means that the patient has only a certain amount of time to file a negligence claim following either the event that caused the injury or illness or from the point of discovering that the problem existed. Statutes of limitations are typically measured in years.

If the patient contributed in any manner to his own injury or illness, and he chooses to file a negligence claim against an EMS provider, then the patient may be found guilty of contributory negligence. In other words, contributory negligence exists when there is a finding that the patient, through his own negligence, caused or contributed to the damage that was done to him.

Medical Direction

Your legal right to function as an EMT is contingent on medical direction. When providing emergency care you should:

- Establish cell phone, telephone, and radio communications with medical direction when appropriate.
- Communicate clearly and completely with medical direction, and follow orders medical direction gives in response.
- Any time there is a question about the scope or direction of care, consult medical direction.

Most areas also have protocols for cooperation between EMS personnel and other public safety services.

Ethical Responsibilities

Ethics is a branch of philosophy specifically directed toward the study of morality, or morals. Morals are concepts of “right and wrong.” A code of ethics is a list of rules of ideal conduct. A Code of Ethics for EMTs was issued by the National Association of Emergency Medical Technicians in 1978. Basically, if you place the welfare of the patient above all else when providing medical care, you will rarely commit an unethical act.

Your ethical responsibilities include these:

- Serve the needs of the patient with respect for human dignity, without regard to nationality, race, gender, creed, or status.
- Maintain skill mastery. Demonstrate respect for the competence of other medical professionals.
- Keep abreast of changes in EMS that affect patient care. Assume responsibility in defining and upholding professional standards.
- Critically review performances, seeking ways to improve response time, patient outcome, and communication. Assume responsibility for individual professional actions and judgment.
- Report with honesty. Hold in confidence all information obtained in the course of professional work unless required by law to divulge such information.
- Work harmoniously with other EMTs, nurses, physicians, and other members of the health care team.

Ethical and moral conflicts may sometimes arise during the performance of your duties. Such an ethical or moral issue may occur when, for example, you are responding to a terminally ill patient who is requesting that no treatment be rendered, and yet the do not resuscitate (DNR) orders presented to you have expired. Legally, you have an obligation to provide care, and yet you may feel an ethical obligation to honor the patient’s wishes to receive no treatment, and a moral obligation to preserve life under any circumstances. In such a situation, obviously, legal and moral criteria would conflict with ethical criteria.

Other situations in which ethical and moral considerations may conflict include mass casualty events where medical care is being rationed as part of the triage process, and cardiac arrest in the wilderness where resources are limited and transportation time to definitive
care is extended. The ethical and moral conflicts that arise as a result of situations like these can be very challenging. It is always best to remember that local protocols and applicable laws should be followed, and that medical direction can be contacted at any time to assist with decisions in these types of situations.

**ISSUES OF PATIENT CONSENT AND REFUSAL**

**Types of Consent**

Under the law, the conscious, competent, and rational patient has the right to accept or refuse emergency medical care. Therefore, it is necessary to obtain consent, or permission, before providing such care. Before emergency care is rendered, the patient must be informed of the care to be provided and the associated risks and consequences. Consent so obtained is termed informed consent.

After introducing yourself, you must indicate to the patient that you would like to perform an assessment to determine what his condition is, provide emergency care, and transport him to a medical facility. You must ask the patient if he understands and has any questions. Ask the patient for his explicit permission before proceeding, even if he was the one who placed the 911 call to EMS. This is particularly important if the assessment or treatment you are recommending is part of a research program in which the interventions in question have not yet been proven effective, which would complicate the process of ensuring that the patient is adequately informed.

Don’t assume that the patient will always consent to all aspects of your assessment, care, and transport. Listen carefully to the patient’s response so that you don’t proceed without his consent. Even on the most routine of calls, if you were to touch a patient’s body or clothing without first obtaining the proper consent, you could be charged with battery, or touching unlawfully. Battery applies to anyone who provides emergency care when the patient does not consent to the specific treatment. (Battery is discussed in more detail later in this chapter.)

In addition to informed consent, there are four other types of consent: expressed consent, implied consent, minor consent, and involuntary consent.

- **Expressed consent** must be obtained from every conscious, mentally competent adult before treatment is started. The patient must be of legal age, competent (meaning that the patient has the mental capacity to make a decision), able to make a rational decision, and informed of the assessment and procedures you will be performing and all related risks. Basically, the patient must receive—in terms the patient understands—all of the information that would affect a reasonable person’s decision to accept or refuse treatment. Although a verbal confirmation of the patient’s consent is preferable, nonverbal cues from the patient, such as nodding when asked if it is all right to perform an assessment, are acceptable as well. It is good practice to document the patient’s approval.

- **Implied consent**, also known as the *emergency doctrine*, occurs when you assume that a patient who is unresponsive or who is not competent or who is unable to make a rational decision (e.g., a patient who is disoriented because of a head injury) would consent to emergency care if he could. Implied consent also applies to the patient who initially refuses your care but then becomes unresponsive, incapacitated, or irrational because of illness or injury. In a true emergency where the patient is at significant risk of death, disability, or deterioration of condition, the law assumes that the unresponsive patient would give consent.

- **Consent to treat a minor** must be obtained from a parent, legal guardian, or other person who has been granted limited rights of decision making by the parent or guardian, such as a teacher, a stepparent, or another authorized caregiver. Depending on state law, a minor usually is any person under age 18 or 21. Minors are considered not legally competent to accept or refuse emergency care; however, if the parent or legal guardian is not present and cannot be reached to provide consent, the concept of implied consent, or the emergency doctrine, is used. It is assumed that the parent or legal guardian would consent to the care of the minor if they were present at the scene. It is imperative that you clearly document the circumstances in making the decision to render emergency care to the minor. You do not need consent of a parent or guardian to treat an emancipated minor—usually defined as a minor who is married, pregnant, a parent, a member of the armed forces, financially independent and living away from home, or one who has been declared emancipated by court decree.

- **Involuntary consent** can be applied when you are dealing with a mentally incompetent adult or with an individual who is in custody of law enforcement or is incarcerated. Gaining consent to assess and treat such individuals often involves a third party, such as a legal guardian, a law enforcement officer, or other officer of the court. If appropriately deemed to be incompetent or in legal custody, the patient does not have the legal right to determine his own care, which makes it necessary to gain consent from the appropriate individual with the legal authority to make decisions on that person’s behalf.

**Advance Directives**

You may sometimes be called to treat terminally ill patients. In some cases, the patient may request—and a physician may order—that no resuscitation measures take place if the heart and lungs stop functioning. Legally, due in part to the federal Patient Self-Determination Act, the patient has a right to refuse resuscitative efforts. An
advance directive (instructions written in advance) against resuscitation, signed by the patient, is a legally recognized document. This document is the wish of the chronically or terminally ill patient not to be resuscitated and legally allows the health care provider to withhold resuscitation.

Common types of advance directives are a do not resuscitate (DNR) order, a living will, a health care durable power of attorney, and physician orders for life-sustaining treatment (POLST). A do not resuscitate (DNR) order is a legal document or order that most often governs resuscitation issues only, whereas a living will is more often used to cover more general health care issues, including the use of long-term life support equipment such as ventilators and feeding tubes. A health care durable power of attorney, also known as a health care proxy, designates a person who is legally empowered to make health care decisions for the signer of the document if he is unable to do so for himself. Decisions by health care proxies usually pertain only to in-hospital or long-term care facility situations.

Physician orders for life-sustaining treatment (POLST) are used in patients with serious or terminal illness who are not expected to survive for longer than 1 year. Unlike a do not resuscitate order that is geared primarily to making a decision to resuscitate or not to resuscitate a patient, POLST is designed to allow the patient to choose and express the level of treatment he desires in the case of deterioration prior to the need for resuscitation. Thus, POLST implies the continuation of life-sustaining treatment with the potential for limitations. For example, the patient may choose the administration of medications but may refuse advanced airway procedures or defibrillation. The POLST is voluntary, not mandatory, for patients. You might find the POLST form in a health care facility, such as a nursing home or long-term care facility, or in a patient’s home. One of the other types of advance directive may accompany the POLST form. The POLST form must be signed by a physician and include dates during which it is valid. The contact information for the physician must also be included. In some states, the POLST may be signed by a physician assistant (PA) or nurse practitioner (NP).

When you are presented with a DNR or POLST, you must determine to the best of your ability whether it is valid and interpret the manner in which the directive should be followed. Check to see that the physician’s instructions are clear, concise, and unambiguous and typed or written in a clear hand on professional letterhead. Phrases like “no heroics” or “no extraordinary treatment” are not clear enough to meet legal requirements. In many jurisdictions and in some states, a standard legal form or varied legal forms are used for DNR orders (Figures 3-1 ■ and 3-2 ■). Be sure to learn the laws and protocols for the state you will function in, since they vary significantly. Some states require a written physician order; others have the patient wear a DNR bracelet. Most states require that the signed DNR or POLST order be present at the scene in order to withhold or limit treatment. Do not simply accept the word of the family. If the DNR or POLST order is not present, you are obligated to perform the resuscitation or needed treatment.

Some states have different degrees of DNR (different kinds of resuscitation treatments refused) and are based on various levels of chronic illness or terminal status. Some patients may request that only selected emergency care or comfort procedures be performed. Typically, oxygen administration is considered a standard comfort measure and should be provided for both the do-not-resuscitate and the modified-support patient. Be sure to learn your local protocol.

Advance directives may be filled with problems for prehospital providers. First, by its very nature, a living will is generally more useful in an institutional setting, such as a nursing home or hospital, where health care providers are aware of it and know the doctor who signed it. In addition, many advance directives require more than one physician to verify the patient’s condition—a requirement that may be difficult to fulfill in the field, even if the advance directive is located. Finally, the time taken to scrutinize an advance directive can take precious moments away from providing resuscitative care.

Issues you may encounter at the scene regarding the DNR or POLST are questions about the validity of the document, interpretation of what care should or should not be provided, and a conflict between the DNR or POLST order and the wishes of a family member. To protect yourself, the best manner to proceed is to (1) consider initiating treatment immediately so that if the issue cannot be resolved you will not be held negligent for not providing care or delaying treatment, (2) contact medical direction for instructions on how to proceed, and (3) continue treatment until the problem has been resolved.

You will be in a much better position if you err by providing treatment rather than by withholding treatment when faced with questions about whether to provide care. In the absence of a valid DNR or POLST order and a physician’s written instructions, you are obligated to begin full resuscitation or needed treatment immediately.

Refusing Treatment Competency

The courts have ruled that a patient has the right to refuse care even if it results in the patient’s death. In order for the patient to refuse care, it is vital that you first determine that the patient is competent. As noted earlier, a competent adult is one who is lucid and capable of making an informed decision. Typically, a patient is deemed to be lucid if he is able to accurately prove orientation to “person, place, and time.” People who display an altered mental status or who are mentally ill or under the influence of drugs or alcohol may be considered
not competent or incapacitated. Many states have laws that provide protection to members of EMS when using implied consent to assess, treat, and transport an incapacitated patient. A competent adult has the right to refuse treatment—verbally, or by pulling away, shaking his head, gesturing you away, or pushing you away—or to withdraw from treatment after it has started.

Under the law, to refuse treatment or transport, a patient must be informed of and fully understand the treatment and all potential risks and consequences of refusal, up to and including the possibility of death if it is a potential risk. Have the patient explain to you what these potential consequences are if treatment is refused. If the patient does not understand the consequences, he would be deemed incompetent and treated under implied consent. Once this has been accomplished, you must attempt to get the patient to sign an official “release from liability” form. The signed form—or a patient’s witnessed refusal to sign the form—is only a part of the documentation of the
DO NOT RESUSCITATE COMFORT CARE PROTOCOL

After the State of Ohio DNR Protocol has been activated for a specific DNR Comfort Care patient, the Protocol specifies that emergency medical services and other health care workers are to do the following:

WILL:
- Suction the airway
- Administer oxygen
- Position for comfort
- Splint or immobilize
- Control bleeding
- Provide pain medication
- Provide emotional support
- Contact other appropriate health care providers such as hospice, home health, attending physician/CNS/CNP

WILL NOT:
- Administer chest compressions
- Insert artificial air way
- Administer resuscitative drugs
- Defibrillate or cardiovert
- Provide respiratory assistance (other than that listed above)
- Initiate resuscitative IV
- Initiate cardiac monitoring

If you have responded to an emergency situation by initiating any of the WILL NOT actions prior to confirming that the DNR Comfort Care Protocol should be activated, discontinue them when you activate the Protocol. You may continue respiratory assistance, IV medications, etc., that have been part of the patient’s ongoing course of treatment for an underlying disease.

Protecting Yourself in Refusal Situations

Complete and accurate documentation is a key factor in protecting yourself from liability for malpractice in the form of negligence or abandonment when a patient refuses treatment. Do the following before you leave the scene:

- **Try again to persuade the patient to accept treatment or transport to a hospital.** Tell the patient why treatment or transport is essential. Be especially
clear and diligent in explaining the possible consequences of refusal (Figure 3-3 ■). Document your attempts to convince the patient as well as the consequences of refusal, and have the patient read aloud from the report to verify understanding.

- Make sure the patient is competent and able to make a rational, informed decision. A patient who is emotionally, intellectually, or physically impaired by illness or injury may not be capable of absorbing all the information you give. Make sure that the patient is not suicidal and not under the influence of drugs, alcohol, or other mind-altering substances.
- Consult medical direction as needed, or as required by local protocol.
- If the patient still refuses, clearly document what was told to the patient, his response, and have him sign a refusal form. In some areas the form must be signed by witnesses (follow local protocol). If the patient refuses to sign the form, attempt to get signed statements of witnesses that the patient refused to sign. (How to document a patient refusal is discussed in greater detail in Chapter 4, “Documentation.”)
- Before you leave the scene, encourage the patient to seek help if certain symptoms develop. If possible, be specific. Say things like “If you have a burning pain in your stomach” or “If you start seeing double.” Avoid technical terms the patient might not understand. Document the fact that you encouraged the patient to seek help later.
- If you are unsure whether the patient is able to make a rational decision, contact medical direction for a consultation as to whether to treat and transport.

Figure 3-2 DNR documents may also take alternative forms, as these examples from Ohio EMS show: (a) a DNR wallet card, and (b) a DNR hospital bracelet.

Figure 3-3 When a patient refuses treatment or transport, be very clear and diligent in explaining to the patient why these are essential and the possible consequences of refusal.
OTHER LEGAL ASPECTS OF EMERGENCY CARE

Negligence

If you breach your legal duty, you create a liability. Two types of liability are criminal and civil. In a criminal liability case, the government, on behalf of the public, brings legal action against the EMT. This may result in a fine or even incarceration. In a civil action, an individual, known as the plaintiff, files a lawsuit against an individual EMT, the EMS agency or company, or others indirectly involved in the care of the patient, such as the supervisor or medical director. These latter individuals are known as the defendants. In a civil action, the defendant is accused of committing a tort, which is a wrongful act, injury, or damage. In civil or tort cases, the plaintiff usually seeks monetary compensation for an act, damages, or an injury that resulted from the EMT’s actions. Most often, lawsuits against EMS involve negligence from a duty not being performed. Negligence is a tort in which there is no intent to do any harm to the patient but in which a breach in the duty to act occurred.

The plaintiff (person who files the lawsuit) has to prove the following four elements:

- The EMT had a duty to act.
- The EMT breached that duty to act.
- The patient suffered an injury or harm that is recognized by the law as a compensable injury.
- The injuries were the result of the breach of the duty (proximate cause).

If the plaintiff cannot prove all four of the elements, the suit will fail and no damages will be awarded.

Two common legal principles are often associated with negligence claims against EMS. The first is res ipsa loquitur, meaning “the thing speaks for itself.” This concept is used in cases where a caregiver’s inappropriate actions are obviously the cause of patient harm. The concept of negligence per se means that an act is considered to be negligent simply because it is in violation of a statute or regulation such as written EMS protocols or approved scope of practice.

Duty to Act

Duty to act, as described earlier in the chapter, is an obligation of the EMT to respond to the scene and to provide emergency care to the patient. Once a patient relationship has been established, which is simply done by the EMT making contact with the patient with the intent to provide emergency care, it cannot be terminated without the consent of the patient.

Breach of Duty to Act

A breach of the duty to act is when the EMT deviates from the standard of care. Negligence is a deviation from the standard of care. Simple negligence occurs when an EMT fails to perform care or when a mistake is made in the treatment. Gross negligence is willful, wanton, or extremely reckless patient care far beyond being negligent or careless. Gross negligence is care that is construed as being dangerous to the patient. An EMT who intentionally causes harm to a patient will be charged with gross negligence. Gross negligence may be so severe that it leads to criminal charges brought against the EMT.

Damages

Damages refers to injuries that are real, demonstrable, and recognizable by the law. The injuries cannot be trivial or minor.

Proximate Cause

It must be determined that the injuries suffered by the patient were the direct result of the EMT’s negligence. This is referred to as proximate cause or causation. By contrast, the patient’s injuries may be a result of the traumatic event or the underlying disease and not the negligence of the EMT.

Intentional Tort

An intentional tort is an action knowingly committed by an individual that is considered to be civilly wrong according to the law. Common intentional torts in EMS are abandonment, assault, battery, false imprisonment, and defamation. The primary difference between an intentional tort and negligence is that negligence is a failure to meet the standard of care that is typically permissible, whereas an intentional tort is knowingly committed.

Abandonment

If you stop treatment of the patient without transferring the care to another competent professional of an equal or higher level of training and certification or licensure, it would be considered abandonment (Figure 3-4). Abandonment can occur in the emergency department if you do not officially transfer the care of the patient or if the transfer is to an inappropriate medical professional. For example, if you arrive at the emergency department, place the patient in an emergency department room, notify the ward clerk or secretary that the patient is there, and then leave the patient, you have just abandoned the patient. You must give an oral report to a physician, nurse, or other health care worker who is qualified to care for that patient and the injuries he has sustained or the condition he is suffering from. Simply moving the patient from your stretcher to the hospital bed does not constitute a patient transfer of care.

An EMT can fully assume the transfer of care of a patient at the scene from a paramedic or Advanced EMT.
only if the patient’s condition or injuries can be managed by the EMT and no advanced life support skills are necessary. On the other hand, if the EMT transfers care of a multisystem trauma patient to a physician who is a dermatologist, the EMT has potentially abandoned the patient. Typically, a dermatologist is not qualified to manage a multisystem trauma patient.

Performing a thorough assessment and always providing care that is in the best interest of the patient will likely eliminate the risk of abandonment.

**Assault**

**Assault** is a willful threat to inflict harm on a patient.

Assault can occur without actually touching the patient. If the patient has the apprehension of bodily harm and the EMT has the ability to do so, it would be considered assault. If the EMT threatens to stick the patient with an epinephrine auto-injector and holds it up in front of the patient, the EMT has potentially created a fear in the patient that the act will be committed.

**Battery**

**Battery** is the act of touching a patient unlawfully without his consent. If you don’t seek and obtain consent, your emergency care might be construed as battery by the patient, even though your intention is good. Without consent, your touching of the patient is unlawful.

**False Imprisonment or Kidnapping**

If a patient is competent and refuses your assessment, treatment, and transport, you must obey his wishes. Taking the patient to the hospital or other medical care facility against his wishes may result in charges of false imprisonment or kidnapping. False imprisonment results from intentionally transporting a competent patient without his consent. It is not necessary that the patient is restrained, it is simply not allowing the competent patient to withdraw from treatment and transport when he desires to do so.

**Defamation**

If you release information to the public in either a written or spoken form that is construed to be damaging to that person’s character, reputation, or standing within the community, you can be charged with defamation. The spoken form of defamation is slander. It is extremely important that you discuss patient, partner, and other emergency issues in a private setting and never in public. Libel is putting a false or damaging statement in written form or via mass media. Follow the correct policies and procedures for complaints against others so that you avoid any litigation involving defamation of character.

As an EMT, it is important to understand these components of a potential or real lawsuit. The best defense against such a suit is to provide emergency care to the best of your ability and to be sure that you understand clearly your scope of practice and the expected standard of care.

**Confidentiality**

Information obtained while getting a patient history, performing a physical assessment, and treating the patient must be kept strictly confidential. The deliberate invasion of a patient’s privacy by an EMT may lead to loss of certification or licensure and other legal actions.

Do not speak to the press, your family, friends, or other members of the public about details of the emergency care you provided to a patient. If you speak about the emergency, you must not relate specifics about what a patient said, who the patient was with, and anything unusual about the patient’s behavior or personal appearance. The same restrictions hold true of information you receive from another member of the EMS system. Confidentiality applies not only to cases of physical injury, but also to cases involving possible infectious diseases, illnesses, and emotional and psychological emergencies.

Releasing confidential information requires a written release form signed by the patient or a legal guardian. You should not release confidential written or spoken information about the patient to someone claiming to be a legal guardian until you have established legal guardianship. By law, you are allowed to release confidential patient information without a patient’s or guardian’s permission if:

- Another health care provider needs to know the information in order to continue medical care.
- An official public health or other governmental agency requires mandatory reporting of information related to your contact with the patient. State laws, for example, commonly require the reporting of incidents of rape, child abuse, elder abuse, neglect, domestic violence, certain communicable diseases, gunshots,
Health Insurance Portability and Accountability Act (HIPAA)

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 is a federal law that protects the privacy of patient health care information and gives the patient control over how the information is distributed and used. HIPAA requires strict adherence to policies and procedures regarding record keeping, storage, access, release, and discussion of patient medical records. EMS systems are required by federal law to have specific policies and procedures in place regarding confidentiality and privacy issues related to patient care records and information. Every person in the EMS system who comes into contact with patients or patient information must be aware of and understand these policies and procedures.

In regard to HIPAA and your practice as an EMT, you will find the following:

- You will be limited to discussing patient-specific information only with individuals with whom it is medically necessary to do so. You cannot go out into the ambulance bay area and begin to discuss your previous patient using specific patient information. There is no medical necessity in doing so and it can be construed as a violation of the HIPAA regulations.
- You will be trained on specific policies and procedures regarding privacy issues by your EMS agency.
- You and the patient will be provided with the patient privacy policies and procedures. It is your responsibility to obtain a signature from the patient acknowledging that he received the information. The form is often included with the insurance release form.
- Your EMS agency will have a designated Privacy Officer who will oversee HIPAA regulations. This is a good resource person to contact regarding issues related to patient-specific information.

If someone is requesting information from you, contact the person in your EMS system who is charged with the responsibility of managing and protecting confidential information. This is the most appropriate person to make the determination as to whether any information should be released and what information can be released and to whom without violating the privacy rights of the patient.

COBRA and EMTALA

The Consolidated Omnibus Budget Reconciliation Act (COBRA) and the Emergency Medical Treatment and Active Labor Act (EMTALA) are federal regulations that ensure the public’s access to emergency health care regardless of ability to pay. They are intended to eliminate any discrimination in who is provided emergency medical care. The regulations prevent “patient dumping,” in which a patient requiring medical care is turned away at the door or transferred to a public hospital because of inability to pay for the services. EMTALA is also known as the “anti-patient-dumping statute.” EMTALA specifically deals with a patient seeking medical care for an emergency medical condition, whether it is due to an injury or an illness. Even though both regulations are primarily geared toward hospital treatment and transfer, EMS personnel are affected by certain aspects of the regulations, especially if the ambulance service is owned and operated by the hospital.

EMS becomes involved when patients are being transferred from a hospital to another medical facility. The key issue is the requirement of the transferring facility to ensure that the patient is stabilized to the best of the medical facility’s ability prior to transfer. This does not mean that the patient cannot be a critical patient or would have no chance of deteriorating en route. However, the transferring facility must ensure that the ambulance crew performing the transfer is qualified and capable of managing the patient and his condition. For example, an EMT crew would not be able to perform a transfer of a patient requiring continuous electrocardiogram monitoring and intravenous infusion monitoring and drug therapy, because these skills are beyond an EMT’s scope of practice. In this case, it would be the responsibility of the EMT to contact his supervisor or follow the EMS policies to notify the transferring facility that the EMT crew is not capable of doing the transfer. If the transfer is done, it could be an EMTALA violation. As an EMT, you have a responsibility to make sure that the patient is stable enough for transfer. If there is a question, it may be necessary for your EMS medical director to contact the transferring physician to discuss whether the EMS crew is capable of conducting the transfer. This must be done prior to loading the patient onto your cot and initiating the patient transfer.

If you are operating a hospital-based ambulance and make a decision to bypass your hospital, which is the closest appropriate medical facility, and take the patient to another medical facility because the patient does not have insurance nor the ability to pay for services, you can be charged with “patient dumping” under the EMTALA regulation.

Protecting Yourself in Transport and Transfer Situations

In an emergency transport to a medical facility, do not make a decision to transport to a specific medical facility based on the patient’s ability to pay. Never report this information over the radio. Do not bypass a medical
facility that is able to treat the patient, unless you are directed to do so by medical direction or the patient or predetermined protocol. Be sure to clearly document the reason for bypassing the medical facility.

If you are performing a transfer between hospitals or medical facilities:

- Get a full and clear report about the patient’s condition.
- Ensure that you are able to provide the level of care necessary during the transport and it is within your scope of practice.
- Obtain the informed consent form signed by the patient or his legal guardian allowing for the transfer.
- Obtain the written certification of transfer that includes the transferring physician’s name and address, facility receiving the patient, and the reason for the transfer.
- Know where you are going and take the quickest possible route.

**Special Situations**

**Donors and Organ Harvesting**

Organs can be donated only if there is a legal signed document giving permission to harvest the organs. A signed donor card is considered a legal document. A sticker affixed to the reverse side of a patient’s driver’s license, or an “organ donor” specification printed directly on the license, provides an intent to donate organs.

A potential organ donor should be treated no differently than any other patient requiring emergency care. The individual is a patient first, an organ donor last. In addition to providing appropriate care, you can assist the organ harvesting procedure as follows:

- Identify the patient as a potential donor based on the type of injuries or illness and treatment that was rendered. Patients who are about to die or who have died within hours are potential organ donors. In each case, however, hospital staff and the patient’s family make the ultimate decision.
- Communicate with medical direction regarding the possibility of organ donation. You can initiate this process by alerting the receiving hospital’s emergency department staff, who will in turn contact other necessary departments.
- Provide emergency care, such as CPR, that will help maintain vital organs in case harvesting is attempted. This is best accomplished by treating every patient equally well.

**Medical Identification Insignia**

A patient with a medical condition, such as an allergy, diabetes, or epilepsy, may be wearing or carrying a medical identification tag, such as a bracelet, necklace, or card (Figure 3-5a ■). Look for them during assessment.

Note that medical identification insignia may also list a phone number you can call for specific treatment and medication requirements.

**Medical Alert Tattoo**

Some people who have traditionally worn a medical alert bracelet have now obtained a permanent medical alert tattoo. Instead of a medical alert bracelet alerting the health care provider to a condition such as diabetes in the unresponsive patient, a permanent tattoo to the wrist, arm, chest, or other location is designed to alert the health care provider (Figure 3-5b ■). These tattoos are not standard in the insignia, lettering, or colors; thus, the EMT may overlook a tattoo as body art rather than a medical alert device.

According to the American Academy of Family Physicians, medical alert tattoos are not yet very pervasive. Also, obtaining a tattoo involves risk, especially for a diabetic with existing wound-healing and infection issues.

During physical assessment of the patient with an altered mental status, it would be prudent to inspect the wrists, arms, ankles, neckline, chest, and other areas of the body for tattoos that may alert you to a medical
condition. If a tattoo is noted on the body of an altered mental status patient, pay close attention to ensure it is not a medical alert tattoo.

**Recognizing Death in the Field**

It is the ultimate responsibility of a physician to determine the time and cause of death. However, in some situations you may have to make a judgment as to whether to attempt resuscitation or not. As a general rule, if the patient is still warm and does not exhibit any obvious signs of death, begin resuscitation. An exception is hypothermia (low body temperature) where the patient’s body is extremely cold and rigid. Hypothermic patients have survived long periods of cardiac arrest and cannot be considered dead until rewarmed.

When dealing with patients holding a DNR order or those with terminal illness, it is necessary to determine the presumptive signs of death. These include the following:

- Absence of a pulse, breathing, and breath sounds
- Complete unresponsiveness to any stimuli
- No eye movement or pupil response
- Absence of a blood pressure
- No reflexes

There are some situations in which signs of death are obvious and resuscitative efforts are not necessary. The obvious signs of death include:

- Decapitation
- Rigor mortis (body becomes stiff within 2–12 hours)
- Decomposition of the body
- Dependent lividity (discoloration of the skin from blood pooling that is effected by gravity) (Figure 3-6 □)

Cases involving violent, unusual, or suspicious causes of death usually require investigation by the medical examiner or coroner. The medical examiner or coroner is usually called for:

- Homicides
- Suicides
- Violent deaths (including suspected child or elder abuse)
- Crash-related deaths (auto, motorcycle, all-terrain vehicle, snowmobile)
- Unusual scene characteristics (e.g., burns, electrocution)
- Sudden infant death syndrome (SIDS)
- Dead on arrival (depending on your local protocol)

It is important to understand your local protocol related to death-in-the-field situations. It is better to err to benefit the patient and begin resuscitation if you have any doubt. Also, be sure you understand the situations in which the medical examiner or coroner must be called to investigate a field death.

**Crime Scenes**

Whenever an EMS is called to a potential crime scene, dispatch should also notify the police. Recognizing a possible crime scene requires a high index of suspicion. As a general guideline, a potential crime scene is any scene that may require police support, including a potential or actual suicide, homicide, drug overdose, domestic dispute, rape, abuse, hit-and-run accident, riot, robbery, gunfire, or potentially dangerous weapons.

Your first concern upon approaching a crime scene should be for your own safety. If you suspect that a crime is in progress or a criminal is still active at the scene, do not attempt to provide care to any patient. Wait until the police declare that the scene is safe. Keep in mind that even when the police declare the scene safe to enter, it can still be potentially dangerous.

Once the scene is secure, your priority is emergency care of the patient. However, also try to avoid disturbing anything that may be considered evidence:

- Take one way in and out.
- Touch only what you need to touch, and remember to tell a police officer if you move or touch anything.
- Move only what you need to move to protect the patient and to provide proper emergency care.
- Do not use a crime scene telephone unless the police give you permission to do so.
- In the absence of police permission, move the patient only if the patient is in danger or must be moved in order for you to provide care.
- Observe and document anything unusual.
- If possible, do not cut through holes in clothing possibly caused by bullets or stabbing.
- Do not cut through any knot in a rope or tie (a possible clue). Cut away from the knot. Do not cover the patient with a sheet.
- If the crime is rape, do not wash the patient or allow the patient to wash. Ask the patient not to change
clothing, use the bathroom, or take anything by mouth, because doing so may destroy evidence. While you cannot force a person to avoid these activities, explain your reasons. Most will cooperate.

As an EMT, you may have a legal duty to report situations in which injury may have resulted from commission of a crime. Learn your local protocols.

**Special Reporting Situations**

You may be required to report certain conditions. Familiarize yourself with the requirements in your state. The following are commonly required reporting situations:

- **Abuse.** Many states require people to report suspected child abuse. Some states have very broad requirements, whereas others require reporting only from physicians. Such statutes frequently grant immunity from liability for libel, slander, or defamation of character as long as the report is made in good faith. In some states, laws also exist regarding the reporting of other kinds of abuse, such as abuse of the elderly and spousal abuse.

- **Crime.** Many states require EMTs to report an injury that may have resulted from a crime or to report injuries such as gunshot wounds, knife wounds, suspicious burns, and poisonings. Your state may also require you to report any injury that you suspect was caused by sexual assault.

- **Drug-related injuries.** Some states require you to report drug-related injuries. However, the U.S. Supreme Court has ruled that drug addiction—not drug possession—is an illness, not a crime.

Other situations you may be required to report include suspected infectious disease exposure, use of patient restraints to treat or transport patients against their will, cases in which a patient appears to be mentally incompetent or intoxicated, attempted suicides, and dog bites. Learn the laws in your state regarding situations you are required to report.

**Baby Safe-Haven Laws**

In the 1990s, an alarming number of infant abandonments occurred, resulting in many infant deaths. At that time, a parent would be criminally prosecuted for neglect or abandonment if an infant was left unattended with the intent of relinquishing custody. As a result of the surge in abandonments, in 1999 Texas enacted the first baby safe-haven law designed to allow a parent to relinquish custody of an unharmed infant to a proper authority. Currently, all states and the District of Columbia have passed baby safe-haven legislation also known as infant abandonment laws.

Baby safe-haven laws vary significantly from state to state. The legal safe-surrender location varies drastically from only designated hospitals in California to a variety of locations to include a hospital, law enforcement agency, fire station, or EMS agency in many other states. It is common for an EMS station to be considered a safe-haven location where an infant can be left with an EMS provider. The age of the infant that can be turned over legally also differs dramatically according to the various state laws. The maximum age varies from only 3 days of age in some states to 1 year of age in North Dakota.

EMS providers must become familiar with the baby safe-haven (infant abandonment) law in their state to determine if their EMS station is a designated safe-haven location and, if it is, what actions are required in case of an abandonment.
care. Expressed consent involves the patient providing some type of acknowledgment or affirmation of the consent. Implied consent is used for patients who are unable to provide consent, such as a patient with an altered mental status but who, if he were able to do so. Minor consent is a type of implied consent used when providing emergency care for minors whose parents or guardians are not present or able to give consent. Involuntary consent involves a third party and is used for those patients who are either mentally incapable or legally prevented from making their own health care decisions.

A competent patient has the right to refuse emergency care or to withdraw from emergency care or transport at any time. It is imperative that the patient is competent and able to make a rational decision before you accept his refusal. Clear and accurate documentation is the key to any patient refusal. Advance directives are predetermined orders that provide for refusal of care or resuscitation, commonly in terminally ill patients. The most common type of lawsuit filed against an EMT is a tort. A tort is a civil action that often involves negligence. Four elements of negligence must be proven for the action to succeed: (1) that there was a duty to act, (2) that there was a breach in that duty, (3) that an injury occurred, and (4) that the injury resulted from the actions of the EMT. Other legal issues that the EMT must thoroughly understand are abandonment, battery, assault, false imprisonment, and defamation.

All information related to a patient on an EMS call must be held in the strictest confidence. Any information that could possibly identify the patient must not be released unless in certain legal and acceptable situations, such as to the medical staff to whom you are transferring care of the patient. The Health Insurance Portability and Accountability Act (HIPAA) has strict rules regarding the storage and release of patient information. You must clearly understand and abide by the policies of your EMS agency regarding patient information.

COBRA and EMTALA are federal regulations that have implications on the public’s access to emergency health care. These regulations pertain primarily to medical facilities; however, EMS may be affected by these regulations when involved in transferring a patient to another medical facility.

Crime scenes warrant special attention by the EMT. The chain of evidence must not be disrupted and evidence must be preserved for law enforcement use. Disrupt a crime scene only if it is necessary to provide immediate emergency care to the patient. It is also important for you to be able to recognize patients who are obviously dead, whether as a result of crime or from natural causes.

Case Study Follow-up

Scene Size-up
You and your partner are dispatched to the scene of an elderly male complaining of abdominal pain. As you scan for hazards, you notice that there is clutter everywhere in the house and that the inside temperature is very cool. Although the patient’s wife is alert, she seems confused. She changes the subject often and keeps asking your partner if she is her daughter Ellen.

Patient Assessment
Your general impression of Mr. Schuman is that he is conscious but disoriented and experiencing abdominal pain. His wife is unsure of his age, so you estimate that he is in his mid-80s. He responds to questions with unintelligible mumbled words. His airway is open; breathing and circulation appear normal. He does not appear to be in acute distress.

Trying to obtain a complete history is impossible, since the patient cannot respond coherently. Instead you perform a rapid assessment, a quick head-to-toe physical exam. Upon palpation of the abdomen, Mr. Schuman tries to force your hand away. If he were competent, you might take this gesture as a refusal of care. However, because of his disorientation, you continue providing care. You measure and record baseline vital signs—breathing rate; pulse; pupils; skin color, temperature, and condition; and blood pressure.

When you try to obtain a medical history from Mrs. Schuman, she does not understand. All she wants to do is show you her porcelain doll collection.

You prepare Mr. Schuman for transport and help his wife find a coat. During transport, you reassess the patient and find no change in his condition.

An Ethical Obligation
After transferring Mr. Schuman to hospital personnel, you contact the hospital’s social service department, as you are required to do in case of elderly abuse or neglect. While you saw no signs of intentional abuse or neglect, you do believe that the Schumans are not capable of caring for themselves, and you are therefore ethically responsible to report the situation to ensure their safety after discharge.

Two weeks later you see the social worker who tells you that Mr. Schuman was diagnosed with a gastric ulcer and organic brain syndrome. Additionally, Mrs. Schuman has been diagnosed with Alzheimer’s disease. Both are now residents of a local extended-care nursing home, under 24-hour supervision. The social worker thanks you and your partner for bringing this case to his attention.
IN REVIEW

1. Define a “do not resuscitate (DNR)” order, and explain how an EMT should respond if presented with such an order.
2. Define three types of consent that must be obtained before emergency care is provided.
3. Explain how to handle a refusal of treatment.
4. Describe what must happen for the EMT to be liable for abandonment or negligence.
5. Describe what it means for an EMT to have a duty to act.
6. List the conditions under which an EMT may release confidential patient information.
7. List some ways in which an EMT can preserve evidence at a crime scene.
8. List situations that an EMT may be required to report.

CRITICAL THINKING

You are called to the scene for a 34-year-old female patient complaining of abdominal pain. Upon arrival, you find the patient lying in bed. She is alert and is holding her abdomen. She states that she is having bad “belly pain” that began about an hour prior to her calling 911. You perform an assessment, place the patient on oxygen, and prepare her for transport. The patient suddenly states, “I don’t want to go to the hospital.”

1. How would you initially gain consent in this patient?
2. How would you manage the patient’s refusal to be transported?
3. What legal issues may you face if you continue with treatment and transport?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • **Preparatory** (Content Area: Documentation)

**COMPETENCY** • Applies fundamental knowledge of the EMS system, safety/well-being of the EMT, medical/legal and ethical issues to the provision of emergency care.

**OBJECTIVES** • After reading this chapter, you should be able to:

4-1. Define key terms introduced in this chapter.
4-2. Describe each of the following purposes served by the prehospital care report (PCR):
   a. Continuity of patient care
   b. Administrative uses
   c. Legal document
   d. Education and research
   e. Evaluation and continuous quality improvement (CQI)
4-3. Describe characteristics, including advantages and disadvantages, of both paper and computer-based (electronic) PCR formats.
4-4. Explain the purposes of the U.S. Department of Transportation (DOT) minimum data set for PCRs.
4-5. List the elements of the DOT minimum data set for PCRs.
4-6. Describe the purpose and contents of each of the following sections of a PCR:
   a. Administrative data
   b. Patient demographics and other patient data
   c. Vital signs
   d. Narrative
   e. Treatment
4-7. Give examples of each of the following types of PCR narrative information:
   a. Chief complaint
   b. Pertinent history
   c. Subjective information
   d. Objective information
   e. Pertinent negatives
4-8. Use common abbreviations and medical terminology accurately in PCRs.
4-9. Explain each of the following legal concerns with respect to the PCR:
   a. Confidentiality
   b. Allowed distribution of the PCR or information included in it
   c. Documenting a patient’s refusal of treatment
   d. Falsification of the PCR
   e. Correction of errors
4-10. Discuss how to handle each of the following situations with respect to the PCR:
   a. Transfer of patient care when returning to service prior to completing the PCR
   b. Multiple-casualty incidents (MCIs)
   c. Special reporting situations, such as infectious disease exposure and suspicion of abuse or neglect
4-11. Accurately and completely record pertinent patient and EMS call information using the SOAP, CHART, and CHEATED methods.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- Minimum data set p. 61
- Prehospital care report (PCR) p. 57
- Pertinent negatives p. 62
- Triage tag p. 68
The Dispatch
EMS Unit 17—respond to 57 Vallejo Road. You have a man injured when his vehicle struck a parked car. Time out is 1321 hours.

Upon Arrival
You and your partner arrive at 1327 hours. As you drive up, you observe four people standing around two vehicles. As you get out of the ambulance, a woman walks over to you from the group. She says, “I called you. That’s my van parked at the curb. I was in the house, heard a crash, looked out, and saw that that car had hit mine. The driver was slumped over the wheel, so I called 911 right away. When I came out of the house, though, he seemed to be all right. He’s the one in the green shirt.” She indicates a man who is pacing around inspecting the damage to the two vehicles.

You and your partner walk toward the man she points to, who appears to be in his mid-30s. He looks at you and says, “Great! As if I didn’t have enough trouble today, I’ve got to deal with you guys! Go away, I don’t need any help!”

How would you proceed to assess, care for, and document this patient contact?

In this chapter, you will learn about the importance of documenting all your encounters with patients as well as the types of information that go into such documentation. Later, we will return to this case and apply what you have learned.

INTRODUCTION
Assessing a patient, treating him, and transporting him to a facility where he can receive necessary medical care are the most obvious parts of the EMT’s job. But there is another function that you will have to perform as an EMT: documentation of data for each patient you come in contact with. That documentation, in the form of written or electronically generated records, will help ensure that the patient receives the best, most appropriate care at the facility to which he is transported. The most common type of record that is prepared and submitted is the prehospital care report (PCR). The type of PCR varies widely among EMS systems and states; however, the information collected is basically the same. The documentation you generate and report via the PCR and other special reporting forms is important for other reasons as well, as you will learn in this chapter.

FUNCTIONS OF THE PREHOSPITAL CARE REPORT
The documentation you assemble and report via the prehospital care report serves a variety of functions. It can be helpful to the patient, to the medical personnel who treat him, to the organizations that have aided him, to scientists and researchers who may never come in actual contact with the patient, and also to you. These functions are discussed in the following paragraphs.

Continuity of Medical Care
The prime reason for high-quality documentation is, of course, high-quality patient care. Reporting the data you have obtained during your contact with a patient and recording, simply but completely, the emergency care rendered helps ensure continuity of care for the patient throughout his need for medical attention. Your documentation gives emergency department personnel the information they need to provide the most appropriate treatment in a timely manner.

When the emergency department staff study the description of a patient’s mental status as well as the vital signs that you obtained and recorded during assessment and transport, they have a baseline against which that patient’s improvement or deterioration can be measured. When they read your account of the patient’s complaint and the signs and symptoms you have marked down, they have a clearer idea of what course they should follow in the treatment of that patient. When they note the interventions you have or have not performed, they know more clearly what measures to take and which would duplicate earlier efforts. In addition, your documentation will provide details from sources to which hospital personnel may have no access (e.g., bystanders, family, or awake patient).

Administrative Uses
The documentation you provide typically becomes a part of the patient’s permanent hospital record. It will be used in preparing bills and in submitting records to
insurance companies. The information may also be used to contribute to statistics regarding the emergency medical service itself, such as the average response time, time on scene for critical trauma patients, or the number of cardiac arrest patients treated each year.

Legal Document

The medical documentation you prepare may also become a legal document. A run in which you were involved may have been the result of a crime. Or the incident may have led to a civil lawsuit. In either case, you may have to appear in court as a witness. Typically, the person who wrote the report will be the one called to testify in court. As such, you will refer to the documentation you generated for that run months or even years earlier. Legible, accurate, and complete documentation will be of major assistance in such cases. In addition, if you are the subject of a lawsuit, your documentation may be an essential element in your defense. Thus, it is important to clearly document objective and pertinent subjective findings, the status of the patient upon arrival on the scene, what emergency care was provided, when the emergency care was provided, and any changes in the patient’s condition upon arrival at the medical facility.

Educational and Research Uses

Your documentation provides data for researchers studying a whole range of issues. Some researchers might be scientists looking to discover positive or negative effects of certain interventions at different stages of patient contact. Others might be experts in administration studying documentation in an effort to deliver services in a more timely or cost-effective manner. The PCR may be used to track or identify various patient presentations and conditions that may require additional education and training.

Evaluation and Continuous Quality Improvement

Reviews of documentation are an integral part of the quality improvement process. Remedial and continuing education courses for EMTs may be based on needs revealed by call documentation. PCRs are also used in medical oversight to determine if EMTs are adhering to protocols and the set standard of care for your area.

COLLECTION OF DATA IN PREHOSPITAL CARE REPORTS

As you can see, the documentation you are responsible for (Figure 4-1) has a variety of important uses. You should be as careful and thorough as possible when assembling it. The prehospital care report is a major piece of documentation you must provide for each patient encounter.

The PCR can have different names in different parts of the country, such as the run report or the trip sheet. The look of the PCR can also vary, depending on the format used for it and the information required on it.

PCR Formats

The most traditional format for the PCR is the written report. This format usually combines check boxes and write-on lines for vital signs and other information that can be entered briefly, along with areas for writing a fuller narrative account of the patient contact (Figure 4-2). An alternative format to the written report that is widely accepted and most commonly used is the computerized direct data entry report. The styles of computerized direct data entry reports may vary. Usually, data are entered directly into a laptop computer or a mobile data device that is synchronized with a computer and then transferred to a large central database. (Figures 4-3a and 4-3b). A smart phone may also have an app for direct data entry (Figure 4-4).

A variation of the computerized report uses an electronic (computer) clipboard. In some “pen-based” computer systems, the computer clipboard has the capability of recognizing and interpreting the user’s handwriting and converting the information he enters into an electronic format. Others offer selection items or lists that require little writing.

Computerized systems offer the promise of storing more information about a patient in a more legible format than written reports. They also allow greater efficiencies in storing, retrieving, and utilizing data the EMT collects. The EMT’s computer can be linked to diagnostic and monitoring equipment; to electronic medical records; to computer-aided dispatch (CAD); and to computer systems handling fleet management, inventory control, e-mail, personnel, and payroll.
On a more basic level, a computerized system can check the EMT's spelling and use of abbreviations, ensuring a more accurate report. Such systems can also monitor data as they are input, alert the EMT if any necessary information has been omitted, and facilitate quality assurance and quality improvement programs as well.

**PCR Data**

Of course, what makes the PCR useful is the information entered on it. That information should provide a complete and accurate picture of your contact with the patient. Remember these two basic rules when filling out any PCR: “If it wasn’t written down, it wasn’t done” (no
one, including emergency department staff, will know it was done; and you won’t be able to prove it was done, for example in a court of law) and “If it wasn’t done, don’t write it down” (which constitutes falsifying information).

Requirements for information on the PCR vary from system to system and state to state, but the types of information required and the sections of the PCR are generally quite similar.

FIGURE 4-2  Beaver Township Fire/EMS, Beaver Township, Ohio: prehospital care report, continued.

The Minimum Data Set
The U.S. Department of Transportation (DOT) has made an effort to standardize the information collected on PCRs. Such standardization will, it is hoped, lead to a higher general level of patient care across the nation. It will also permit more meaningful comparison and analysis of data from various systems, which may...
Patient Information
- Chief complaint
- Level of responsiveness (AVPU)—mental status
- Blood pressure for patients greater than 3 years old
- Skin perfusion (capillary refill) for patients less than 6 years old
- Skin color, temperature, and condition
- Pulse rate
- Respiratory rate and effort
- Patient demographics (age, sex, race, weight)

Administrative Information
- Time the incident was reported
- Time the unit was notified
- Time of arrival at the patient
- Time the unit left the scene
- Time the unit arrived at its destination (hospital, etc.)
- Time of transfer of care

Another important element in establishing the minimum data set is the use of accurate and synchronous clocks. This means that all elements of an EMS system should use clocks or timekeeping devices that are accurately set and agree with each other. Dispatch’s clock should not show one time, while the watches of the EMTs show another. Accurate timekeeping helps in the gathering of accurate medical information; for example, synchronous timekeeping by dispatch and the ambulance crew makes it easier to determine how long a patient has been in cardiac arrest before CPR or defibrillation was initiated. Accurate timekeeping can also be critical if administrative issues or legal questions over quality of care arise.

Many systems already require gathering the information included in the DOT’s minimum data set. Such information is usually arranged in the following sections on the PCR.

Administrative Information
The administrative information section of the PCR is sometimes referred to as the run data. It usually includes the administrative information listed in the minimum data set. In addition, it may also include:
- The EMS unit number and the run or call number
- Names of crew members and their levels of certification
- The address to which the unit is dispatched

Patient Demographics and Other Patient Data
The next major section of the PCR contains primarily demographic patient information and other pertinent data about the patient. Most systems will require the following information:
- The patient’s legal name, age, sex, race, birth date
- The patient’s home address
- The insurance or billing information
- The location where the patient was found
- Any care given before the arrival of the EMTs
**Vital Signs**

A third major division of the PCR documents the patient’s vital signs. On many forms, boxes are provided for checking off or writing in information. Computerized PCRs have drop-down menus that can be selected or data fields where the information can be entered. This section usually includes much of the patient information called for in the minimum data set. Various systems may also require additional data.

Ideally, at least two complete sets of vital signs should be taken and recorded. It is important to note the patient’s position at the time the vital signs were taken (e.g., supine, standing, sitting). It is also critical to record the times at which the vital signs were obtained.

**Patient Narrative**

The next part of the PCR gives more detailed information about the patient and his problem than allowed for in check boxes or drop-down menus and limited data fields. This critical information sets the tone for the entire course of assessment, treatment, and documentation that will follow. This narrative section contains the following:

- The patient’s chief complaint—This should be in the patient’s own words or in the words of a bystander, if the patient is unresponsive. Put such statements in quotation marks (“My leg hurts”) on the report.
- The patient’s history or a description of the mechanism of injury—These data will include an account of when the chief complaint began and how it has progressed, along with other details of the patient history.

In this section of the PCR, you will create a brief but thorough picture of the patient and his problem. Remember that you are recording details for other medical personnel to use, not presenting your own conclusions about an incident. Careful observation of the patient and the scene as well as intelligent questioning of the patient and bystanders are essential. These methods will provide both objective and pertinent subjective information for the narrative section.

**Objective** information is measurable or verifiable in some way. It might be a reference to the patient’s pulse rate or a statement that the patient has discoloration below both eyes. A sign is an objective observation.

**Subjective** information is based on an individual’s perceptions or interpretations. Subjective information in the narrative section may come from either the patient or the EMT. For example, a patient might say, “I feel light-headed.” An EMT might observe, “The patient seems to be in pain.” A symptom is a subjective finding.

Subjective information should be pertinent; that is, it should relate to the medical circumstances. It should not include attempts at diagnosis. Nor should it include irrelevant observations such as, “The patient’s husband offered to transport the patient.”

In questioning a patient, be alert to pertinent negatives. These are signs or symptoms that might be expected, based on the chief complaint, but that the patient denies having. A pertinent negative might be a patient’s denial of pain after an automobile crash or a lack of difficulty in breathing in a case of chest pain. By noting the absence of pertinent signs and symptoms, you will provide the medical team that takes over care of the patient a fuller picture of his condition.

The narrative should briefly document the physical assessment in the order it was performed (i.e., head, neck, chest, and so on). Include pertinent information about the scene as well as about the patient. Note, for example, the presence of bottles of medication, a suicide note, or a collapsed ladder. If sensitive information is being reported, be sure to note the source of the information. As an example, if a wife states, “My husband is addicted to heroin,” note the wife as the source of the highly sensitive but very important information.

Document the time and findings of each patient reassessment. This is especially important when attempting to identify trends in the patient’s condition.

Write the narrative in a simple, direct style. Do not use radio codes or nonstandard abbreviations. Table 4-1 lists common standard abbreviations used by the EMT. A much more comprehensive list of abbreviations is found in Table 4-2. However, because of the possible confusion associated with the interpretation of even the acceptable abbreviations, it is preferred that the EMT write out each term or word instead of using an abbreviation.

Be especially careful in your use of medical terminology. Make sure you are using the proper term and that you are spelling it correctly. Look up spellings and definitions in a medical dictionary if you have any doubts. If you are still uneasy about the meaning of a term, or whether it applies to the situation you are describing, use everyday language instead. Mistakes in medical terminology can cause confusion and lead to delays or errors in treatment.

### Treatment

The final information for entry on the PCR involves the treatment provided to the patient. This section should detail in chronological order all treatments you administered to a patient, what time they were administered, and indications of how the patient responded to that treatment. This information should be written in a clear narrative style, following the guidelines cited earlier.
in “Patient Narrative.” An emergency physician, nurse, paramedic, or fellow EMT should, by reading your report, be able to learn what treatment was provided, the time it was provided, and whether the patient has improved or deteriorated since then.

It is important to include any other information that may be a local or state requirement. Specific data may be collected to enter into registries or other local or state databases for the purposes of research, education, or service performance.

## LEGAL CONCERNS

As noted earlier, the PCR is a legal document. Some legal issues involving documentation are discussed in the following sections.

### Confidentiality

You must use care and discretion when handling any information about a patient. Remember that, as detailed in Chapter 3, “Medical, Legal, and Ethical Issues,” confidentiality is the patient’s legal right. The PCR and the information on it are considered confidential. Do not show the form or discuss the information on it with unauthorized individuals. Be familiar with the limitations of release of information mandated by the Health Insurance Portability and Accountability Act of 1996 (HIPAA).

### Distribution

Follow state rules and local protocols in distributing the PCR and any additional information about a patient encounter. By law, you are generally permitted to provide confidential information about a patient to a health care provider who needs the information in order to continue care, to the police if they request information as part of a criminal investigation, to a third party if the information is required on a third-party billing form, or in court if required by a legal subpoena.

A copy of the PCR is generally left with the patient in the emergency department or receiving facility. The original is typically retained by the emergency medical services. A third copy may be forwarded to medical oversight or a quality improvement official. Electronic data may be transferred and distributed in a similar manner.

### Refusal of Treatment

Chapter 3, “Medical, Legal, and Ethical Issues,” discussed various issues that arise when a patient refuses treatment. As noted there, any competent adult has the right to refuse treatment. But legal questions often arise after the fact about whether the patient was truly competent. For this reason, you must make extra efforts with a patient who is refusing treatment to ensure that he fully understands what he is doing. You must also document your efforts completely.

1. **When you encounter a patient who refuses treatment,** try to perform as much of an assessment as possible. The extent of the examination will often depend on what the patient will allow you to do. Doing so may give you information to use in explaining what might happen if the patient continues to refuse treatment.

2. **Before leaving the scene always try to make one more effort to persuade the patient to go to the hospital.** Ensure that the patient can make a rational, informed decision and is not under the influence of alcohol or other mind-altering drugs, is not suffering from the effects of an illness or injury, and is not suicidal.

3. **Inform the patient as clearly as possible why he should go to the hospital.** Explain what may happen if he does not go. Discuss the possible consequences of delaying or refusing treatment. Confirm that the patient understands this information.

4. **If the patient still refuses treatment,** discuss the situation with medical direction as directed by local protocol. Such discussion can provide two major benefits. First, the patient may consider that the doctor’s opinion carries more weight than the EMT’s, so he may change his mind and accept treatment. Second, if the patient still refuses transport, the doctor can give the EMT direction in providing medical assistance at the scene.

5. **If the patient still refuses to accept emergency care and/ or transport,** document in the PCR any assessment findings you have made, any emergency medical care you have given, and the explanation you gave the patient of the consequences of failing to accept care and/or transport (including potential death). Document if the patient refused to allow you to complete any or all of your assessment and if the patient refused any or all emergency care you intended to provide to him. You must document that the patient is alert and oriented to time, place, and person/self so there is no question that the patient understood the information and instructions you gave him. Then have the patient sign a refusal-of-care form (Figure 4-5). You should also have a family member, police officer, or bystander sign the form as a witness. If possible, obtain witnesses’ addresses in case they must be contacted.

6. **If the patient refuses to sign,** have a family member, police officer, or bystander sign the form verifying that the patient refused. Each section of the refusal-of-care form must be completed.

7. **Before leaving the scene,** you should offer alternative methods of getting care (e.g., taking a taxi to a clinic or asking a friend or family member for help in seeing a doctor).

8. **Finally,** explain that you or another EMT crew will be happy to come back if the patient changes his mind and decides to accept treatment. It would be prudent to explain signs the patient may exhibit or symptoms he may complain of if the condition worsens.
Falsification

The PCR documents the nature and extent of emergency medical care an EMT provides. It is meant to be a thorough and accurate record. Any mistake in care must be highlighted on the PCR. In such a situation, the EMT might be tempted to falsify the PCR.

Such falsification of information on a PCR should never occur. When an error of omission or commission occurs, the EMT should not try to cover it up. Instead, the EMT should document exactly what did or did not happen and what steps were taken (if any) to correct the situation. False information may lead to suspension or revocation of EMT certification or license and, potentially, to criminal charges.

More importantly, falsification of patient data will compromise patient care. Other health care providers can get an incorrect impression of the patient’s condition from false assessment findings or a falsified report of treatment.

Certain areas of the PCR are more commonly falsified than others. One of those areas is vital signs. An EMT might, for some reason, neglect to take a set of vital signs and be tempted to make up numbers to cover the omission. Another area is treatment. An EMT might assist a patient in taking a medication without the approval of medical direction. Or he might have neglected to give oxygen to a patient complaining of chest pain. In the former case, the EMT might be tempted to leave out of the PCR the fact that he assisted in administration of medicine, while in the latter he might want to write in that oxygen was given. In none of these cases should the record be falsified. Although the changes might appear insignificant, they could have catastrophic results.

Correcting Errors

Even the most careful EMT will occasionally make errors in filling out the PCR. When such an error is discovered while a paper report is being written, draw a single horizontal line through the error, initial it, and write the correct information beside it (Figure 4-6). Do not try to erase or write over the error. Such actions could be interpreted as attempts to cover up a mistake or falsify the report.

When an error is discovered after the report form is submitted, draw a single horizontal line through the error, preferably using different-colored ink. Add a note with the correct information. Initial the entry and include the date and time of the correction. If information was omitted, the EMT should add a note with the correct information, the date, and the EMT’s initials. Be sure to bring such changes to the attention of those to whom the incorrect report was submitted.
Most electronic PCR formats provide a method to amend the report that includes a date and time stamp if an error is discovered. If there is no way to electronically amend or submit an amended report, correct a printed copy using the traditional methods described for a paper report and resubmit the PCR as a corrected copy.

**SPECIAL SITUATIONS**

There are certain circumstances in which the standard PCR will not be appropriate. Examples of such circumstances are discussed in the following sections.

**Transfer-of-Care Report**

Upon delivery of the patient in the medical facility, under ideal circumstances the EMT will complete a full PCR containing all of the patient data, obtain a transfer-of-care signature from the medical professional who is assuming patient care responsibility, and leave a copy of the full report with the facility. However, this ideal situation may not always exist. It may be necessary for your unit to return immediately to service to answer an additional call, precluding the EMT from submitting a full PCR until a later time.

Some computerized report formats do not provide the ability to print a hard-copy report to leave with the medical facility. Upon completion, the computerized report is downloaded into the EMS system’s main computer and printed at a later time, then delivered or faxed to the medical facility.

In such cases, an abbreviated transfer-of-care form or “drop report” may be used to provide minimal patient data and collect a transfer-of-care signature. This abbreviated report can be used as a reference at a later time when completing the full PCR. A copy of the transfer report should be submitted with the full PCR.

**Multiple-Casualty Incidents**

During multiple-casualty incidents (MCIs), such as plane crashes or multiple-vehicle collisions, rescuers are often overwhelmed with the number of patients requiring treatment. The needs of these patients can sometimes conflict with the need for complete documentation. In these cases, there may not be enough time to complete the standard PCR before turning to the next patient.

Each EMS system has its own MCI plan. Those plans should have some means of recording important medical information and keeping that information with the patient as he is moved for treatment. Often such basic information as chief complaint, vital signs, and treatment provided is recorded on a triage tag that is attached to the patient. Information from the tag can be used later to complete the PCR. In MCI situations, the PCR will usually be less detailed than those of more typical, single-patient runs. Local plans should contain guidelines for what is expected in the PCRs in those situations. More information on MCI situations will be provided in Chapter 45, “Multiple-Casualty Incidents and Incident Management.”

**Special Reports**

In some circumstances, EMTs must fill out special documentation other than the usual PCR. These cases require the notification of agencies and local authorities beyond the usual health care network. Such cases might include the following:

- Suspected abuse of a child or elderly person
- Possible exposure to an infectious disease (e.g., meningitis, hepatitis, TB, HIV)
- Injury to an EMS team member
- Other situations that the EMT feels might require special documentation or informing of another agency

State laws and local protocols usually outline the circumstances in which special reports are required and often provide a form for such reports. These special reports should be accurate, descriptive, and objective; should not lead to any conclusions; should contain the names of all individuals, services, and facilities involved; and should be submitted in a timely manner. Always keep a copy for your own agency’s records. The procedure for distribution of such reports is also established by local protocol.

**ALTERNATIVE DOCUMENTATION METHODS**

There are several alternative methods used to organize information on the prehospital care report. Three of these alternative methods are known by the mnemonics SOAP, CHART, and CHEATED—as described in the following sections.

**SOAP**

The mnemonic SOAP stands for subjective, objective, assessment, and plan. These components can be used to organize the information that needs to be documented on the prehospital care report.

**S—subjective**—refers to information that the patient must tell you. This is information or symptoms that you cannot see or feel during the physical exam. Symptoms are the patient’s descriptions of how he is feeling. For example, the patient states, “I have terrible head pain.” You have no physical evidence of the head pain, only the description provided by the patient.
O—objective—refers to information that you identify in the physical examination through inspection, palpation, and auscultation. Your sense of smell will also provide objective information. This kind of information is referred to as signs. For example, a large laceration is a sign of injury. Whether the patient complains of any pain or not, you are able to see the laceration and make an objective assumption that an injury has occurred.

A—assessment—refers to the field assessment, the general idea you form about the patient’s condition on the basis of the information you have collected from the subjective and objective components, along with a scene assessment, the chief complaint, and any other information provided by bystanders or family. For example, you may surmise that a patient with a history of diabetes who is acting bizarrely, is not oriented, and has pale, cool, and clammy skin as well as tachycardia may be suffering from a low blood sugar level (hypoglycemia).

P—plan—refers to the plan of action and the emergency care provided to the patient. In the patient with diabetes, it may include the administration of oral glucose and oxygen and transportation to a medical facility.

The SOAP method may be used by EMS systems as the basis for standard reporting practices. Some variations of the SOAP method exist and may be used to meet the specific needs of an EMS system. For example, the mnemonic SOAPIE may be used. The I refers to intervention and the E refers to evaluation. This would allow for a better account of the ongoing assessment that is conducted on the patient.

CHART

Another mnemonic used to organize documentation is CHART, which stands for the following:

C—chief complaint of the patient
H—history of the patient (including the SAMPLE history)
A—assessment findings gathered in the primary assessment, secondary assessment, detailed physical exam, and ongoing assessment

R—Rx for treatment that was provided to the patient
T—transport—any change in the patient’s condition en route and the type of transport (e.g., emergency)

CHEATED

A more specific mnemonic used to organize documentation is CHEATED. This mnemonic organizes the documentation as follows:

C—chief complaint
H—history of the patient (including the SAMPLE history)
E—exam—information that was found in the physical examination of the patient
A—assessment—the field impression you derive by processing the history and physical exam findings and determining a condition the patient may be suffering from
T—treatment that was provided to the patient
E—evaluation—the information that is found during the ongoing assessment and any identified improvement or deterioration of the patient’s condition
D—disposition—the transfer of patient care at the medical facility or to another health care provider

SOAP, CHART, and CHEATED represent different methods to organize the information expected to be documented on the prehospital care report. Whatever system is developed, it is important that it is used to ensure the most accurate documentation of the patient information.

MEDICAL ABBREVIATIONS

Medical abbreviations can be used in your documentation on the prehospital care report. Abbreviations can save room and time when writing the PCR. However, it is extremely important that you use only universally accepted medical abbreviations and that you do not make up your own, because your made-up abbreviations might imply a different meaning or no meaning to other health care professionals who will read your report. Table 4-2 lists standard medical abbreviations.
Documentation serves many functions in emergency medical services. It is used for the continuity of patient care, case reviews, a permanent record, legal purposes, and education and research. All documentation must be completely accurate and represent what truly occurred during the patient assessment and management. It must be legible and contain only acceptable objective and pertinent subjective information.

Documentation is also imperative in reporting refusal of care and transport. Your documentation may make the difference in proving that you fully informed the patient prior to his refusal. Because documentation is so vital to record keeping, and your PCR is a patient record, there is absolutely no tolerance for falsification of any information contained within the report. If an error is made, you must follow the recommended method for making corrections to the PCR.

Case Study

**Scene Size-up**
You have been dispatched to the scene of an automobile accident. As you pull up, you observe a group of people standing by two vehicles. You note that the left front end of one vehicle that is in the street, a midsize car, is dented in and the headlight is smashed. The right rear of the other, a minivan at the curb, is also dented and the light on that side is broken. A woman explains that the car struck her parked van while she was inside the house, and that she called 911. Your partner inspects the car for signs of damage and clues to mechanism of injury sustained during the collision. You note that the man who was driving the car is in his mid-30s and has a slight bruise on the left side of his forehead. Despite this evidence of trauma, he is on his feet. He angrily says he does not want your help.

**Primary Assessment**
You remain calm and polite in spite of the driver’s initial outburst. You and your partner introduce yourselves, and you say, “I understand that you’ve had some problems. We’re certainly not here to give you any more trouble. We just want to make sure you’re OK. Are you feeling all right? Do you have any pain, Mr. . . . ?”

“Makynen. Paul Makynen,” he replies, appearing to grow calmer. “I’m sorry I flew off the handle, but it’s been a bad day. I’ve been running late. I was on my way to see an important client when a dog ran out into the street. I braked and swerved. I missed it, but hit that van instead. I just bumped my forehead on the inside of the door frame. It’s a little sore, I’m a little achy, but that’s all. Look, I appreciate your coming out, but I’m OK, really. And I’ve got to get going.”

You note from the patient’s answer that he is alert, responsive, and having no difficulty in breathing. However, you recall that the woman who called 911 said that right after the collision Mr. Makynen was slumped over the wheel. You ask him if he thinks he lost consciousness, however briefly. He denies it and says, “Nah, I just put my head down on the wheel because I was disgusted.” You see no signs of bleeding. His skin appears to be normal in color and dry. Mr. Makynen refuses your partner’s attempt to provide manual stabilization of his head and neck but permits you to assess his radial pulse. You find that his pulse is slightly rapid but strong and regular and that his skin is warm to the touch.

**Secondary Assessment**
You explain to Mr. Makynen that you would like to do a physical exam to check for any signs of injury. He becomes angry again and says, “Come on. I’m okay. I don’t need that.” You ask if you can take his blood pressure and other vital signs, and he says, “No, no. Look, I really feel fine.” He also refuses to answer any of the SAMPLE questions except to deny any pain or other symptoms. He rejects your suggestion that he be transported to the hospital.

You are not ready to give up yet. You tell Mr. Makynen that, because of the injury to the head, it would be best that he be checked by a doctor. You explain that head injuries often display no signs at first but can later develop into potentially life-threatening situations. He interrupts to say, “Fine, I’ll take that chance, but I am leaving.” Your partner discreetly calls dispatch to say, “Patient is refusing emergency care and transport. We will inform you of our status shortly.”

**Documentation**
Meanwhile, recognizing that you are going to have no success in persuading Mr. Makynen to accept care, you explain to him that before he leaves he must sign a refusal-of-care form. You prepare the PCR and the refusal forms. On the PCR, you note the mechanism of injury, the bruise to the forehead, and your initial findings regarding his alert mental status, open airway, adequate breathing, absence of bleeding, pulse that is rapid but regular and strong, and skin color.
Case Study Follow-up

temperature, and condition indicating adequate perfusion. You write that the patient denies pain and, although a witness reported that he was slumped over the wheel after the collision, the patient denies losing consciousness.

You document that, at this point, the patient refused further care. You also note your recommendation that the patient see a doctor and your explanation of the possible consequences. You add that the patient still refused further care.

You show the PCR to Mr. Makynen and allow him to read it and the refusal form. While he is doing so, your partner explains the situation to the owner of the van and another bystander and asks them to witness the refusal. They agree and, after Mr. Makynen signs the refusal form, they also sign where you indicate.

As Mr. Makynen gets into his car, you suggest again that he see his personal physician as soon as possible. You add that if he suddenly feels dizzy or in pain, he shouldn’t hesitate to call 911 for assistance.

Your partner contacts dispatch and states that the patient has refused treatment and transport. Your unit is now clear and in service.

IN REVIEW

1. Explain the various uses of the documentation that the EMT generates after a patient contact.
2. Describe two common formats for the prehospital care report.
3. Explain the origin and purpose of the minimum data set.
4. Explain what the phrase “accurate and synchronous clocks” means and why they are important.
5. Define pertinent negatives.
6. List the steps you should take if a patient refuses treatment.
7. Explain the meaning and importance of the following two documentation rules: “If it wasn’t written down, it wasn’t done” and “If it wasn’t done, don’t write it down.”
8. Describe how errors on PCRs should be corrected.
9. Explain how a multiple-casualty incident can affect EMT documentation.
10. Describe circumstances in which an EMT might be expected to file special reports with other agencies.

CRITICAL THINKING

You arrive on the scene and find a 36-year-old female patient who complains of severe abdominal pain. The patient is alert and oriented. Her vital signs are BP 88/64 mmHg; HR 128 bpm; R 24 and adequate chest rise; skin is pale, cool, and clammy; SpO2 is 96% on room air. Her radial pulses are weak. She states the pain began suddenly about 4 hours ago and has progressively worsened. She was sitting on the couch watching television when it began. Nothing makes the pain better or worse. The pain is dull and aching, and it is intermittent. The pain does not radiate.

The patient rates the severity of her pain as 8 on a scale of 1 to 10. She states she feels light-headed and dizzy every time she stands up, and she also feels nauseated. She has no known allergies and takes over-the-counter Prilosec for heartburn. She has no pertinent medical history. She reports she had her tonsils removed when she was 10 years old. She has had nothing to eat or drink for about 7 hours. She states that she has “not felt real good” for a few days, and other than the time she has spent working at her desk at work, she has been at home on the couch. Her pupils are equal and sluggish to respond. She has no jugular venous distention (JVD). Her abdomen is rigid and tender. There is no evidence of trauma to the abdomen. She has good motor and sensory function in all four extremities. Her peripheral pulses are very weak.

En route to the hospital, the patient begins to close her eyes. You must verbally instruct her to open her eyes. Her BP is 82/62 mmHg, HR 134 bpm, and R 26 with adequate chest rise. The pulse oximeter is providing an “error” reading. Her skin is more pale, cool, and clammy and her radial pulses are barely palpable.

When preparing to write the PCR, you note her name as Jennifer Sampson. She lives at 1321 Oakridge Drive in Smithville, Ohio.

1. What can this information be used for?
2. How will the medical personnel in the medical facility use the information?
3. What will your EMS use the information for?
4. What would you document in the patient information section of the minimum data set?
5. What would you document in the administrative section of the PCR?
6. What information would you write in the patient narrative section?
7. Should any of the information not be reported in the PCR?
8. If you were to make a mistake while writing the PCR, how would you correct it?
9. If the PCR contains a box for a third set of vital signs, what would you document in this patient?
10. How would you collect additional information needed for your PCR?
Communication

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Preparatory (Content Areas: EMS System Communication; Therapeutic Communication)

**COMPETENCY** • Applies fundamental knowledge of the EMS system, safety/well-being of the EMT, medical/legal and ethical issues to the provision of emergency care.

**OBJECTIVES** • After reading this chapter, you should be able to:

5-1. Define key terms introduced in this chapter.
5-2. Discuss the purposes and characteristics of each of the following EMS system communication components:
   a. Base station
   b. Mobile radios
   c. Portable radios
   d. Digitalized radio equipment
   e. Mobile data terminals
   f. Cell phones
5-3. Describe the responsibilities of the Federal Communications Commission.
5-4. Explain the importance of EMS system communication equipment maintenance.
5-5. Given a radio transmitter/receiver, demonstrate the standard ground rules for radio communications.
5-6. List key points in an EMS call at which you should communicate with dispatch.
5-7. Deliver a concise, organized radio report that clearly conveys essential information to medical direction or the receiving facility.
5-8. Describe the process of receiving and confirming an order from medical direction over the radio.
5-9. Identify situations in which you should make additional contact with medical direction or the receiving facility after providing an initial radio report.
5-10. Given a scenario, deliver an oral report to transfer care of the patient to a receiving facility or another EMS provider.
5-11. Given a scenario, demonstrate effective communication that enhances team dynamics.
5-12. Discuss the advantages and disadvantages of using radio codes.
5-13. Convert back and forth between military time and standard clock times.
5-14. Communicate using commonly used radio terms.
5-15. Describe the components of the communication process.
5-16. Discuss factors that can enhance or interfere with effective communication.
5-17. Give examples of each of the following techniques of therapeutic communication:
   a. Clarification
   b. Summary
   c. Explanation
   d. Silence
   e. Reflection
   f. Empathy
   g. Confrontation
5-18. Given a scenario, engage in an effective communication process with a patient.
5-19. Recognize the potential messages that may be communicated via nonverbal behaviors.
5-20. Describe the uses, advantages, and disadvantages of open-ended and closed questions.
5-21. Analyze your communications with a patient in a scenario to recognize the following pitfalls in communication:
   a. Leading or biased questions
   b. Interrupting the patient
   c. Talking too much
   d. Providing false assurance
   e. Giving inappropriate advice
   f. Implied blame
5-22. Discuss considerations for each of the following situations:
   a. Communicating with a patient’s family
   b. Getting a noncommunicative patient to talk
   c. Interviewing a hostile patient
   d. Cross-cultural communications
   e. Language barriers
   f. Communicating with children and elderly patients
INTRODUCTION

Years ago, the job of ambulance crews was simply to transport patients to hospitals. The crews had no responsibility to provide emergency care to those patients. With such a limited role to perform, crews had no need for sophisticated communications systems.

Reliable communications systems are an essential part of EMS today. They permit EMTs to reach their patients more quickly and allow hospitals to prepare appropriately for the arrival of those patients. They allow EMTs to call for necessary resources and they also link EMTs in the field with doctors, enabling the EMTs to provide more lifesaving services than ever through contact with medical direction. For these reasons, understanding EMS communications skills and equipment is an essential part of the EMT’s job.

In order to communicate effectively with a patient, it is important to understand the principles of therapeutic communication. EMTs should be able to communicate in a manner that establishes a positive relationship with their patients. EMTs must also be able to adjust the way they communicate with patients who have special needs.

Case Study

The Dispatch
EMS Unit 2—proceed to 101 Bate Road. You have a man bleeding heavily in the driveway there. Time out is 1128 hours.

“Dispatch, this is Unit 2,” your partner radios back. We copy and are responding to 101 Bate Road. Our ETA is 10 minutes. Do you have any more information on the nature of the problem?”

Dispatch replies, “Unit 2, that is negative. The caller said he was bleeding and was in the driveway. That was all.”

Upon Arrival
Bate Road is in a semirural area with houses widely spaced. Because the dispatch gave little information, you approach the scene with extreme caution, realizing that some act of violence may have led to the call. You park a short distance up the road from the house, which has an attached garage. There is one car in the driveway and only one person in sight, a man sitting on a bench next to the garage and clutching his hand. The scene appears secure, so you pull up and back into the driveway. Your partner radios, “Unit 2 to dispatch. We are on the scene at 101 Bate Road.” Dispatch responds, “Unit 2 on the scene at 1137 hours.”

Because the dispatch said there was bleeding at the scene, you and your partner put on gloves and protective eyewear. Your partner grabs the jump kit and you both step out. As you walk up the driveway, you scan the scene carefully, looking for any signs of possible danger. The garage door is open, and you can see a workbench at the back of it. No one else is in sight. Meanwhile, the man, who appears to be in his 40s, has gotten off the bench and is walking toward you. You note that his right hand is wrapped in a blood-soaked rag and that his shirt and pants are bloodstained.

How would you proceed to assess and care for this patient? How would you use your communications skills and equipment during contact with the patient?

During this chapter, you will learn about the elements of emergency prehospital care communications and communications systems. Later, we will return to the case and apply the procedures learned.
Components of an Emergency Communications System

While emergency prehospital care communications systems vary considerably, many of them employ the components discussed in the next sections.

**Base Station**

The base station serves as a dispatch and coordination area and ideally is in contact with all other elements of the system (Figure 5-1 ■). The base should be located on a suitable terrain, preferably a hill, and be in proximity to the hospital that serves as a medical command center. Base stations generally use relatively high power output (80 to 150 watts) and should be equipped with a suitable antenna within a short distance. The antenna plays a critical part in transmission and reception efficiency. Transmission power levels are limited by the Federal Communications Commission, and the minimum usable signal level for reception is limited by man-made noise. A good antenna system can compensate to some degree for these limitations.

**Mobile Radios (Transmitter/Receivers)**

Mobile radios (transmitter/receivers) are vehicle-mounted devices used to communicate within the EMS system. Mobile transmitters usually transmit effectively at lower power than base stations (typically 20 to 50 watts) (Figure 5-2a through d ■). Most mobile radios are able to transmit over a 10- to 15-mile range on average terrain. The transmission distance of a mobile radio is affected by the terrain and is reduced in mountainous areas or where there are many tall buildings. Mobile transmitters with higher outputs have proportionally greater transmission ranges than those with lower outputs.

**Portable Radios (Transmitter/Receivers)**

Portable, handheld transmitter/receivers are useful when you are out of your vehicle or in the patient compartment and must stay in communication with the base, with one another, and with medical direction (Figure 5-3 ■). Such portable units may also be used by medical direction when they are stationed at a hospital that has no radio. Portable units usually have power outputs ranging from 1 to 5 watts and thus have limited range, although the signal of a handheld transmitter may be boosted by retransmission through a repeater.

**Repeaters**

Repeaters are devices that receive transmissions from a relatively low-powered source such as a mobile or portable radio and rebroadcast them at another frequency and a higher power. Repeaters make communications possible in EMS systems that cover a wide area or where the terrain makes transmission and reception of signals difficult (Figure 5-4 ■). Repeaters can be located in emergency vehicles or at fixed sites throughout the area covered by the EMS system.

**Digital Equipment**

Digitalized radio equipment is common today. With such equipment, an encoder breaks down sound waves into unique digital codes, like those used in CD players, while a decoder recognizes and responds to only those codes. This equipment allows different mobile and base stations to operate on the same broadcast frequency, allowing more messages to be transmitted over those already crowded frequencies.

Included in digital communication is the use of a mobile data terminal that is mounted in the cab of the ambulance. Instead of a voice dispatch to a scene, the mobile data terminal receives a signal from the digital radio and displays the information on the terminal screen. Some equipment will also print the information on a hard copy. The EMT can reply to the dispatch by either hitting a designated button that indicates the unit is en route, or replying by voice communication. The data terminals are often installed to reduce the number of necessary radio transmissions. The EMT may also indicate that he is on the scene, en route to the hospital, at the hospital, and back in service by simply pushing a designated button. This is designed to facilitate communication and not replace voice communication.
Cell (Wireless) Phones

Some EMS communications systems use cell phones as a means of communication. Cell phones transmit and receive through the air rather than over wires (Figure 5-5). They operate in the following manner: A particular geographical service area is divided into a network of slightly overlapping geographical cells that range from 2 to 40 square miles in size. The cells are the equivalent of radio base stations. When a telephone moves beyond one cell’s range, service to it is automatically picked up by another cell.

Benefits of cell phones include excellent sound quality, availability of channels, easy maintenance, and, often, increased privacy of communications. They are often used as backups to an existing radio system or where the expense of establishing a radio system is too great. The major disadvantage of cellular phone systems for EMS use is that they are part of the public phone
system and can easily be overwhelmed during multiple-casualty disasters.

**Broadcast Regulations**

The Federal Communications Commission (FCC) has jurisdiction over all radio operations in the United States, including those used by EMS systems. The FCC licenses individual base station operations, assigns radio call signs, approves equipment for use, establishes limitations for transmitter power output, assigns radio frequencies, and monitors field operations. The FCC has also set regulations to limit interference with emergency radio broadcasts and to bar the use of obscenity and profanity in broadcasts.

**System Maintenance**

Because a properly working communications system is at the heart of effective delivery of emergency medical services, regular maintenance of the system’s equipment is a must. The equipment should not be mishandled or unnecessarily exposed to harsh environmental conditions. Regular cleaning with a damp cloth and a mild detergent should be part of the maintenance program. The communication equipment should also be checked to ensure that it is not drifting from its assigned frequency.

Mobile and portable radios and telephones that operate on battery power should be checked on a daily basis. Most equipment uses rechargeable batteries.
Freshly charged batteries should be inserted every day, while the removed batteries are put in the recharger. In addition, a backup set of fully charged batteries should always be on hand.

EMTs need to be able to communicate with dispatch, contact one another, and consult medical direction. If the equipment is not functioning properly, these communications may be impaired and may cause significant problems within the system. Your service should have some provision for backing up its communications system. Such provisions might include the availability of emergency generators at the base and repeater stations in case of power failure or the supplying of cell phones to EMS units for use in cases of radio failure.

As technology changes, new equipment becomes available that may have a role within the EMS system. This new equipment may have benefits and features that currently do not exist in your present system and may eventually improve the quality of your EMS system’s communication (Figure 5-6).

COMMUNICATING WITHIN THE SYSTEM

As an EMT, you will be expected to communicate not just with your partners and patients but also with EMS dispatch, medical direction, and medical personnel at receiving facilities (Figure 5-7). What follows are some guidelines for communication within the EMS system.

Ground Rules for Radio Communication

Whenever you are communicating via your radio to other members of the EMS system, there are some basic ground rules to keep in mind. These rules apply to your communications with any part of the EMS system and serve as a standard format for the transmission of information.

1. Turn on the radio and select the correct frequency. Use EMS frequencies only for EMS communication.
Reduce background noise by closing your vehicle’s windows.

2. Listen before transmitting. This ensures that the channel is clear of any other communications and avoids interruption of someone else’s transmission. Adjust the radio to a proper volume.

3. Push the “press to talk” (PTT) button and wait 1 second before speaking. This will allow time for system repeaters to operate and will ensure that the initial part of your communication is not cut off.

4. Speak with your lips about 2 to 3 inches from the microphone. Speak clearly, calmly, and slowly in a monotone voice that can be completely understood (Figure 5-8 ■).

5. Address the unit being called by its name and number, and then identify your unit by name.

6. The unit being called will signal for you to begin transmission by saying “go ahead” or whatever is the standard in your system. If the unit being called responds with “stand by,” that means wait to transmit until further notified.

7. Keep transmissions brief. If a transmission should take more than 30 seconds, pause for a few seconds to allow other units the chance to use the frequency for emergency transmissions.

8. Keep your transmission organized and to the point. Use plain English and clear text. Avoid slang and meaningless phrases such as “Be advised.” Courtesy is assumed, so one should limit saying “Please,” “Thank you,” or “You’re welcome.” Also avoid codes or agency-specific terms unless their use is an accepted part of your system’s communications.

9. When transmitting a number that might be confused with another (13 might be heard as 30), say the number (“thirteen”), then the individual digits that make it up (“one-three”).

10. Avoid offering a diagnosis of the patient’s problem. Instead, remain impartial and give only the objective information (observable, verifiable information such as vital signs, chief complaint, medications the patient has) and relevant subjective information (opinions or judgments such as, “The patient appears to be in extreme pain”) that you have gathered during your patient assessment.

11. When receiving orders or information from dispatch, medical direction, or other medical personnel, use the “echo” method. Immediately repeat the order word for word. Doing so will ensure that you have received the information accurately and understand it.

12. Always write down important information, such as addresses, orders to assist with medication, and so forth that you receive from other parts of the EMS system.

13. The airwaves are public, and scanners, which are popular, can pick up radio and cell phone messages. Protect your patient’s privacy by not using his name in your transmissions. Use objective, impartial language in describing the patient’s condition. Do not make personalized comments about the patient or his condition; such statements could be grounds for a slander suit. Do not use profanity on the air.

14. Use “we” rather than “I” in your transmissions; an EMT rarely acts alone.

15. Use “affirmative” and “negative” rather than “yes” and “no” in transmissions. The latter words can be difficult to hear.

16. When you are finished, say “Over.” Wait for confirmation that the other unit has received your message and does not need to have anything repeated.

Phone/Cell Phone Communication

If your system utilizes phone or cell phone communications to deliver pertinent information, the content and format of the information should be treated similarly to that provided during radio communications. The EMT should be familiar with the cellular technology being used and should be aware of the cellular dead spots in the area. There should be another plan in place in case a cellular transmission fails while giving a report or communicating with another agency. The EMT should also be familiar with important and commonly utilized telephone numbers, such as those for medical direction, the local hospital emergency departments, and the dispatch centers.

Communicating with Dispatch

Your first contact on a run will probably be with your EMS system’s dispatch—perhaps a certified Emergency Medical Dispatcher (EMD). Dispatch is the public’s point of contact with the EMS system, usually via the 911 universal emergency telephone number. It is the job of dispatch to obtain as much information as possible about an emergency, to direct the appropriate
emergency service(s) to the scene, and to advise the caller on how to manage the situation until help arrives.

A newer technology that may provide the responding EMS crew with additional information is Advanced Automatic Collision Notification (AACN), found as a standard feature in many newer car models. Not only can this technology accurately indicate that the vehicle was involved in a crash, but also it can provide the exact location of the vehicle and indicate change in velocity during the crash, direction of force, airbag deployment, rollover, and occurrence of multiple collisions. Some or all of this information may be made available to the responding EMS unit. In addition, according to the 2009 Centers for Disease Control and Prevention Guidelines for Field Triage of Injured Patients, this information may be used to predict injury severity, transportation mode (air versus ground), and medical facility destination (level of trauma center) prior to the arrival of the EMS crew.

In many systems, dispatch records all conversations with initial callers, police, fire personnel, EMT units, and receiving facilities. These communications can all become part of the legal record if a call should eventually lead to a court case. This is another reason to be sure that your radio conversations are professional, concise, and accurate.

You will also note that dispatch gives the time after most communications with you. This will help you in providing times for your written report of a run. Accurate recording of time during a run can also be critical if the run should lead to a lawsuit.

The information that dispatch provides to you will assist you in doing your job. But remember that dispatch coordinates the different parts of the EMS system. Dispatch also needs information from you to ensure that all those parts work together efficiently. Communicate with dispatch at the following points:

1. To acknowledge that the dispatched call information was received.
2. To advise dispatch when the unit is en route to the call.
3. To estimate your time of arrival at the scene while en route and to report any special road conditions, unusual delays, and so on.
4. To announce your unit’s arrival on the scene, to request any needed additional resources, and to help coordinate the response. (In some systems, the unit must also report when they reach the patient after arriving on the scene.) Dispatch should be contacted if there is a prolonged on-scene time without communication.
5. To announce the unit’s departure from the scene and to announce the destination hospital, number of patients transported (if more than one), and estimated time of arrival at the hospital.
6. To announce your arrival at the receiving hospital or other facility. If you were meeting at a rendezvous point, announce your arrival there.
7. To announce that you are “clear” and available for another assignment after the patient has been transferred.
8. To announce that you are leaving the hospital and are on your way back to the station.
9. To announce your arrival back at the station.

Communicating with Health Care Professionals

On a run, you may have to communicate with medical personnel at various times via your radio. The majority of these communications will be with your system’s medical direction and with personnel at the facility to which you are transporting a patient. In some systems, you may need to communicate with other EMS providers to transfer care of the patient.

Communicating with Medical Direction

In some EMS systems, medical direction may be at your receiving facility. In others, it will be at a separate location. You will often be expected to consult with medical direction on a run. There are cases in which medical direction may give you permission to assist in administering a patient’s prescribed medication or may direct you to administer a medication from the ambulance’s stock. Medical direction may also suggest procedures that you should follow with a patient or tell you not to perform other procedures.

Radio communications between EMTs in the field and their medical direction should be organized, concise, and pertinent. It is helpful to have an efficient and effective standard format for communicating patient information over the radio. This ensures that significant information is related in a consistent manner and that nothing is omitted. When communicating with medical direction, provide the following information:

1. Your unit’s identification and its level of service: BLS (basic life support) or ALS (advanced life support). You may identify yourself as the provider giving the report.
2. The patient’s age and sex.
3. The patient’s chief complaint.
4. A brief, pertinent history of the present illness, including scene assessment and mechanism of injury.
5. Major past illnesses.
6. The patient’s mental status.
7. The patient’s baseline vital signs.
8. Pertinent findings of your physical examination of the patient.
9. Description of the emergency medical care you (and others) have given the patient.
10. The patient’s response to the emergency medical care.
11. The patient’s current condition.
12. Request for further actions/interventions at the receiving facility.
To ensure that you have communicated accurately to medical direction and that you understand their directions completely, follow these additional guidelines:

- Be sure that the information you provide to medical direction is accurate and that you report it in a clear, understandable way. Remember that your patient’s life may depend on the decisions that medical direction makes with that information.
- After receiving an order from medical direction to administer a medication or follow a procedure with a patient, repeat the order back word for word. This applies to things that medical direction tells you not to do as well.
- If you do not understand an order from medical direction, ask that it be repeated. Then repeat it back to medical direction word for word.
- If an order from medical direction appears to be inappropriate, question the order. Possibly medical direction misunderstood something in your description of the patient’s condition or misspoke in prescribing a course of action. Asking questions may clarify the communication and may prevent the administration of a harmful medication or the application of an inappropriate procedure.

**SBAR** is a method of organizing your communication into a standard format that would be particularly useful when communicating with medical direction, especially if you are seeking further orders. SBAR is an acronym for situation, background, assessment, and recommendation. **Situation** refers to the problem or reason why you are calling and the patient’s chief complaint. **Background** is a concise description of the past medical history and the patient’s response to treatment to that point. **Assessment** includes pertinent subjective and objective assessment findings such as mental status, vital signs, neurologic findings, blood glucose level, and Glasgow Coma Score. **Recommendation** is basically what you are requesting for the patient, such as an order to administer another nitroglycerin spray. The following is an example of the SBAR method of organizing communication:

<table>
<thead>
<tr>
<th>Situation</th>
<th>Dr. White, this is EMT Stockdale. I have a 56-year-old male patient complaining of chest discomfort.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Background</td>
<td>He has a history of a previous MI and has a stent. His pain, which is typical of his previous MI, began 50 minutes ago. He experienced no relief of pain following administration of three nitroglycerin sprays or oxygen therapy. He was also given a 180 mg aspirin tablet.</td>
</tr>
<tr>
<td>Assessment</td>
<td>He is alert and his blood pressure is 168/98 mmHg. His heart rate is 108 bpm. He is very anxious.</td>
</tr>
<tr>
<td>Recommendation</td>
<td>I would like to administer another nitroglycerin spray.</td>
</tr>
</tbody>
</table>

The primary advantage of using SBAR is that medical professionals involved in the communication have a certain expectation of what information will be given and how the information is to be communicated. This standard approach dramatically lessens the chance for miscommunication, lack of communication, or misunderstanding.

**Communicating with the Receiving Facility**

As an EMT, you will also be expected to communicate with medical personnel at the receiving facility to which you are transporting a patient. Staff at the facility need as much pertinent information about the incoming patient as possible to prepare for his arrival and to ensure continuity of care. Doctors and nurses may need to assign rooms and set aside equipment for your patient. They may need to request additional personnel to help with the patient upon your arrival. If, through your communication with the receiving facility, you provide an accurate picture of your patient’s condition, the correct decisions about the assignment of resources can be made at the facility.

The information the EMT conveys to the receiving facility is quite similar to that given to medical direction. When you are about to leave the scene of a call and begin transport, contact the receiving facility with this information:

1. Your unit’s identification and its level of service (BLS, ALS). You may identify yourself as the provider giving the report.
2. The patient’s age and sex.
3. The patient’s chief complaint.
4. A brief, pertinent history of the present illness, including scene assessment and mechanism of injury.
5. Major past illnesses.
6. The patient’s mental status.
7. The patient’s baseline vital signs.
8. Pertinent findings of your physical examination of the patient.
9. Description of the emergency medical care you (and Emergency Medical Responders) have given the patient.
10. The patient’s response to the emergency medical care.
11. The patient’s current condition.
12. Your estimated time of arrival at the facility.

As you transport the patient to the receiving facility, you will continue to reassess him and record your findings. Depending on your local protocol, you may be expected to communicate those findings, especially if the patient’s condition is deteriorating, while you are en route. Make it a routine practice to report any deterioration or improvement to the receiving facility. In some systems, it may be necessary to notify the receiving hospital when you have arrived at their facility.
The Oral Report

Once you are at the facility and turning the patient over to staff there, you will deliver an oral report that takes into account your reassessment findings (Figure 5-9). That oral report should summarize the information you already broadcast to the facility, along with updated information from your reassessment. Key items to include are the following:

- The patient's chief complaint
- The patient's vital signs taken en route
- Treatment given to the patient en route and his response to it
- Pertinent history not given in the earlier report to the facility

In addition to your oral reports to the receiving facility, both over the air and in person, you must also supply the facility with a copy of a written report. This document is known as the prehospital care report (PCR), as discussed in Chapter 4, "Documentation."

Transferring Patient Care to Another EMS Provider

Sometimes it is necessary to transfer care of a patient from one EMT to another in the field. Make sure that you follow all your agency's policies and protocols when transferring patient care to another EMT or paramedic. When other EMS personnel arrive on the scene to take over patient care, it is important that you identify yourself and give them a verbal report. This report should include the following:

1. The patient's current condition
2. The patient's age and gender
3. The patient's chief complaint
4. A brief, pertinent history of what happened
5. A description of how you found the patient
6. Any major past illnesses
7. Vital signs you obtained from the patient
8. Pertinent findings of the physical exam
9. Any emergency medical care that was given
10. The patient's response to any emergency medical care that was provided

After giving your report, make sure you ask if they need any additional information before you leave the scene. Also, do not forget to obtain any information that you will need to complete your documentation of the call and transfer of care. Some agencies may request a copy of your documentation before you leave the scene so it can be included with their report to the facility.

The SBAR method of standardized communication can be particularly useful during the handoff from other emergency medical responders at the scene, when seeking orders from medical direction, and when providing the transfer report on arrival at the medical facility.

TEAM COMMUNICATION AND DYNAMICS

The EMT is a member of a team of health care professionals. At many scenes, the EMT will function as part of a team composed of fire, rescue, law enforcement, and other professionals. In these situations, the EMT is expected to communicate professionally with those working within the team as well as with others. Good team communication not only improves how the team accomplishes its goals, it also improves the quality of services provided to the patients and the community.

Taking Charge

It will be necessary for you as an EMT to take charge confidently at the scene to which you have been called. Your personal appearance and professional manner from the time of your arrival throughout your stay at the scene will help communicate to bystanders and family members, as well as to the patient, that you are in charge.

If you arrive on the scene and observe that the patient is alert and that no life-threatening conditions are present, it may be appropriate to be briefed—before you make direct contact with the patient—by the Emergency Medical Responder, whether that person is a police officer, a relative, or someone who has given first aid. This need not take more than a minute.

If the patient is unresponsive and life-threatening injuries are observed, go directly to the patient. Ask questions of the bystanders as you provide emergency care.

If a doctor is present or if fire-rescue personnel or police are also on the scene, an orderly transfer of authority must occur so that you are not simultaneously engaged in a dispute and attempting to care for the patient. Sometimes just asking a clear question like, "We’re Emergency Medical Technicians. Is there anything we can do for you?" will help to avoid confusion.
need to know before we provide emergency care?” will let rescue and police personnel brief you quickly and allow you to take over patient care. If a doctor is present, say, “We’re certified EMTs, Doctor. How can we help?” In any situation, the EMT must be the advocate for good and proper patient care and not allow secondary issues to interfere with it.

Radio Codes

Some EMS systems use radio codes, either alone or in combination with messages in plain English. Radio codes can shorten radio air time and provide clear and concise information. They can also allow transmission of information in a format not understood by the patient, family members, or bystanders. There are, however, several disadvantages to the use of codes. First, the codes are useless unless everyone in the system understands them. Second, medical information is often too complex for codes. Third, some codes are infrequently used, so valuable time may be wasted looking up a code’s meaning.

Some EMS services still use the Ten-Code system (for example, “10-4” meaning “received and understood”). Published by the Associated Public Safety Communications Officers (APCO), it is used primarily for dispatch and occasionally in EMS. Many EMS systems, however, have abandoned all codes in favor of standard English.

Times

U.S. Department of Transportation guidelines call for the use of accurate and synchronous clocks by EMTs. As an aid to ensuring such accuracy and synchronicity, most systems use military time rather than standard a.m. and p.m. designations in radio and written reports. Military time is a very simple system and correlates with standard time as follows:

1:00 A.M. to 12 Noon = 0100 to 1200 hours
1:00 P.M. to Midnight = 1300 to 2400 hours

Examples of the military time system include the following:

1427 hours is 2:27
0030 hours is 30 minutes after midnight

Radio Terms

Radio conversations can be shortened by the use of one- or two-word phrases that are universally understood and employed. The following is a list of frequently used radio terms:

**Break**—afford a “pause” so that the hospital can respond or interrupt if necessary
**Clear**—end of transmission
**Come in**—requesting acknowledgment of transmission
**Copy**—message received and understood

**ETA**—estimated time of arrival
**Go ahead**—proceed with your message
**Landline**—refers to telephone communications
**Over**—end of message, awaiting reply
**Repeat/say again**—did not understand message
**Spell out**—asking sender to spell out phonetically words that are unclear
**Stand by**—please wait
**10-4**—acknowledging that message is received and understood

**THERAPEUTIC COMMUNICATION**

Principles of Patient Communication

**Communication** is an essential part of your job as an EMT. You must be able to communicate effectively with all those you come in contact with while you are on a call. Communication involves more than just what you say. Communication is a dynamic process that incorporates verbal and nonverbal expressions into meaningful messages that are received by others. These messages are composed of thoughts, ideas, information, and emotions that are sent by one person and interpreted by another. Many factors such as gender, culture, age, environment, and personal experience can influence how one sends and interprets these messages. As an EMT, you need to know how to communicate with patients in a manner that establishes a positive relationship. Once a positive relationship is formed, it becomes easier for you to get the information you need from the patient and to provide care.

The Communication Process

Communication begins when an individual, the **sender**, uses words and symbols to create a message. This process of converting information into a message is called **encoding**. The encoded message is sent to the **receiver**, the individual for whom the message is intended. To understand the message, the receiver must decode it. The process by which a message is translated and interpreted by the receiver is called **decoding**. Decoding is affected by the receiver’s individual perceptions, values, and experiences. It is important that the intended meaning of the message be accurately decoded. The more closely the decoded message matches the intended meaning of the encoded message, the more effective the communication will be.

One way to ensure that the message is received as it was meant to be is through **feedback**. Feedback is any information that an individual receives about his behavior. It can be verbal or nonverbal, positive or negative. The receiver creates feedback to the message he received, then encodes that feedback to the original
sender. The sender, in turn, must decode the feedback in order to interpret it. Once again, decoding of the feedback message is affected by the decoder’s personal perceptions, values, and experiences. This exchange of messages and feedback is repeated throughout the communication process.

**Communication Responses**

It is necessary to develop and establish a good rapport with your patients. Putting the patient and yourself at ease allows for better communication. If you treat your patients with respect, compassion, and empathy, your communication with them will be easier and more accurate.

As an EMT, you should understand that each patient will interpret your messages differently. You should also be aware that you need to interpret the patient’s messages as closely as possible to the way he intends them. Actively listening to your patients will help you to accurately interpret what they mean to tell you and to understand what types of responses are most appropriate for each patient.

Some techniques that may facilitate communication with your patients are:

- **Clarification.** Sometimes it is necessary for the EMT to ask more questions in order to clarify the meaning of a message. Sometimes the patient may be so upset that he can’t verbally express what he means to say. Let the patient know that you didn’t understand what he meant, and ask him to say it again. If the message is not clear to you, communication will be impaired.

- **Summary.** It may be necessary to summarize your patient’s messages in order to understand what he means. Rephrase what you have interpreted, and repeat it to the patient. You can ask if your summary is close to what he meant or felt. If your summary does not accurately represent the patient’s feelings or ideas, ask for clarification.

- **Explanation.** As an EMT, you will have to explain many things in response to your patient’s questions. You should present the information in a way that he can understand it. Make sure you consider the patient’s age and any language barriers when forming your response. You will also need to explain what he should expect to happen before it occurs. This will help establish trust and a good rapport between yourself and the patient. Watch for verbal and nonverbal clues that he does or does not understand your explanations.

- **Silence.** Sometimes what we don’t say is more powerful than what we do say. Silence allows time to think and gain insight into what is occurring. It also allows time for patients who may be slow to answer because of language or other barriers to formulate an appropriate verbal response. Silence for an outgoing individual may be therapeutic, but for an individual coping with depression it may not be beneficial. As an EMT, you must consider your patient’s needs when utilizing periods of silence.

- **Reflection.** This technique allows you to let the patient know that you understand what he said or feels. It redirects the patient’s feelings and statements back to the patient in a way that promotes empathy, respect, and understanding.

- **Empathy.** Empathy is the ability to recognize and understand someone else’s state of mind or feelings. It is the ability to put yourself in the patient’s shoes. It is a characteristic that EMTs need to possess. Although you cannot actually experience what your patient has experienced, empathy enables you to understand how it has affected him.

- **Confrontation.** Sometimes it is necessary to confront a patient about discrepancies in his feelings, attitudes, beliefs, or behaviors. This is NOT to be accomplished through anger and aggression by the EMT. It may require an EMT to be more assertive than usual, but with the assertion comes a desire to help the patient overcome his crisis and understand his own feelings and behaviors. Even when you need to confront or challenge him, always respect the patient and act in the patient’s best interest.

- **Facilitated communication.** Facilitated communication is done by supporting the patient’s hand, wrist, arm, shoulder, or elbow so that he can select letters on a letterboard, electronic keyboard, or other communication device to communicate with you. People with certain developmental or sensory disabilities may require you to act as a facilitator. You must be careful not to influence what is being communicated by the patient to you.

**Communicating with the Patient**

When you arrive on a call, you may find the people at the scene injured, frightened, anxious, and possibly angry or in shock. These are all high-intensity emotions that can make getting information from and delivering information to people difficult. To establish effective face-to-face communications with people in such circumstances, keep in mind the three Cs: competence, confidence, and compassion. If you convey these qualities in what you say and do, you will get better cooperation and have to deal with fewer hostile or irrational responses. As an EMT, it is important that you build a good rapport with your patient to promote trust. Patients expect that you will provide professional care and have a true concern for their needs.

**Patient Contact**

Developing rapport and communicating with your patient begins when you arrive on scene. It includes everything from how you present yourself physically to
what you say and do from that first moment on. Follow these guidelines when communicating with the patient:

- First impressions are critical. Before you arrive on scene, make sure that your physical appearance positively reflects the health care professional you are. Just as your patient’s appearance makes a first impression on you, your appearance makes an impression on your patient. Dress professionally and approach your patients with compassion and confidence.
- When you approach the patient, introduce yourself as you want to be called. Ask for the patient’s name. Also ask what he wishes to be called. With older people, err on the side of formality—“Mrs. Lubeck” or “Mr. Perez”—since they may consider it disrespectful for a stranger to address them by their first name. Remember to continue to use the patient’s name throughout your contact with him. This shows respect and conveys interest in the patient as an individual.
- Introduce the rest of your team to the patient. Although you may not be able to give the names of every responder on the call, make sure the patient knows which agencies and personnel are helping him. Your partner and anyone working closely with the patient should be identified by name.
- Be sure also to say, “I’m going to help you. Is that all right?” This will help in gaining consent for treatment as discussed in Chapter 3, “Medical, Legal, and Ethical Issues,” and Chapter 4, “Documentation.”
- Don’t be surprised if a patient says, “No!” or “I’m okay!” when you ask about providing assistance. Usually the resistance will be a form of denial or another defense mechanism because he is simply frightened or confused. Defense mechanisms are psychological coping strategies the person may use to protect himself from unwanted feelings or thoughts. Although these defense mechanisms are used by patients to protect themselves, they can create barriers to communicating and interacting with them. Keep talking calmly and try to shift the patient’s focus or use distraction by saying something like, “Looks like an accident happened here. I can see there’s something wrong with your shoulder. Does it hurt?” or “Your husband called us because he’s worried about you. Would it be all right if we talked about it for a minute or two?”
- Speak clearly, calmly, and slowly. People who are under stress or in medical shock process information more slowly. Speak distinctly and simply. Try to use language an average person will understand rather than medical terminology, codes, jargon, and abbreviations. Try to speak calmly and give orders quietly. Emotions can escalate quickly in tense situations.
- Use a professional tone of voice. Speak with concern and compassion. Modulate your voice if needed. Raise your voice only if the patient is hard of hearing. Avoid tones that might be perceived as flippant, sarcastic, angry, or otherwise unprofessional.
- Respect the patient’s privacy. Try to limit the number of bystanders around the patient. Speak so the patient can hear you, but do not broadcast information to the rest of the crowd. Some patients may be reluctant to discuss their condition, even around friends or family, so try to interview the patient alone if possible.
- Limit interruptions when communicating with your patient. This will give you the chance to actively listen to your patient and help you communicate better with him. Allow interruptions only when absolutely necessary for the patient’s care.
- Think about the position you assume in relation to the patient and be aware of your own body language. Be aware of the space between you and your patient.
- Try to control the physical environment. Make sure that the lighting is sufficient for you and the patient to see each other. Limit outside noise and interference so that you may actively listen to what your patient has to say. Turn off distracting equipment if it is not necessary for patient care. Ask for your patient’s permission to turn off the television or other loud devices if they interfere with your ability to hear and communicate.
- Be courteous. Patients and bystanders are often emotionally unstable. Explaining what you are doing, giving them choices when possible, being honest with them, and apologizing for necessary discomfort are ways of allowing them a sense of control in the situation.
- Actively listen to your patient. When a patient asks you questions, reply as fully as you can, explaining when you cannot answer a question. Also, give the patient ample time to answer a question before you ask another one.
- Be honest with the patient. If you are able to earn and maintain the patient’s trust, it is often easier to provide the care that he needs. If that trust is lost, patient care may become more difficult to provide.

The Patient Interview

It is important to conduct an interview that will provide you with as much information as possible about your patient and the emergency. To do this, you need to know what types of questions to ask your patients and how to ask them. When you combine effective interviewing techniques with genuine compassion and concern, you will be able to gather the information you need to help your patients.

Nonverbal Communication

As stated earlier, your communication with the patient begins before you speak a word. Just as your physical appearance conveys professionalism, your nonverbal communication, or body language, conveys meaning too. Nonverbal communications such as those listed
Posture. The way you position yourself in relation to your patient will impact how you are perceived. Use your arms and body position effectively. Approach the patient with open arms, open hands, and relaxed shoulders. That will convey a message of concern, confidence, safety, and care. If you cross your arms, point your finger, clench your fists, or shake your head negatively, you signal that you are angry, hostile, disgusted, or uncomfortable around the patient (Figure 5-10a ■). Such signals limit communication and often make the interviewing process uncomfortable and unproductive. Position yourself at the same level as your patient to indicate that you see the patient as your equal (Figure 5-10b ■). If you stand over him, it suggests that you see yourself as an authority figure, which may be intimidating. An exception to this is when a patient seems hostile or aggressive, in which case you may prefer to keep your eye level above his to assert your authority. When addressing children or the elderly, positioning yourself below their eye level may help them feel more comfortable and secure.

Distance. Be aware of the distance between you and your patient. In American culture, the space within less than 1½ feet of an individual is called the intimate zone. Entering your patient’s intimate zone may be seen as threatening, even though you have to be close in order to make a proper physical assessment. It is best to use a more personal distance of about 1 to 4 feet from your patient when you are communicating with him verbally. Ask and inform your patient about what you need to do before you enter his personal or intimate space. Most patients understand the need for you to enter this space. If you meet resistance, step back until you establish a better rapport and the patient trusts you to enter his space. An acceptable social distance to talk to another person without shouting would be about 4 to 12 feet. In public, most people will keep 12 feet or more between themselves and another person, but it sometimes cannot be done. Other cultures do not share the same spatial zones as Americans. Misunderstandings can occur when too much or too little space is used. Consider a patient’s culture and nonverbal responses when invading his personal space. Observe your patient’s eye contact and other reactions when you approach him. This may provide a guide as to how much distance to maintain between you.

Gestures. Gestures are nonverbal body movements that convey meaning to others. They are composed of movements from any part of the body, including facial expressions. Facial expressions can include winking, smiling, rolling your eyes, pushing your eyebrows together, or any other expression that conveys an emotion. Your patient's facial expressions can indicate fear, anxiety, pain, sorrow, relief, or dismay. It is important that you watch and acknowledge your patient’s expressions as indications of how he feels. A warm, kind smile indicates your concern and welcomes communication from your patient.

Eye contact. Make and maintain eye contact when you are speaking with the patient. Doing so helps to communicate your interest and concern. However, you should be aware that some cultures (Asians, Native Americans, Indochinese, and Arabs, for example) consider direct eye contact impolite or aggressive; you may have to modify your behavior if you note that a patient is reluctant to make eye contact with you.

Haptics. Haptics is the study of touching. Touch can be one of the most effective ways to help calm the patient and express your compassion and empathy. Holding a hand, patting a shoulder, giving a hug, or laying your hand on a forearm can be more...
powerful than words if done sincerely (Figure 5-11). Most patients welcome a warm touch from the EMT who has come to help them. A patient’s age, gender, culture, and experiences may influence how the touch is perceived. Maintaining eye contact can help you decide if the patient will allow you into his intimate space so that when you need to touch the person, that touch is not perceived as encroachment.

Both the EMT and the patient communicate verbally and nonverbally throughout the entire emergency call. Remember that nonverbal communication is individually interpreted by both of you and is exchanged just as verbal communication is. Culture, age, gender, and experience influence how nonverbal communication may be perceived. Sometimes, what is said verbally is contradicted by nonverbal expressions. When this contradiction occurs, the meaning of the message is primarily derived from what was expressed nonverbally.

Asking Questions

Most patients are more than willing to talk to you. Most will provide answers to the questions you ask without hesitation. Make sure that you ask one question at a time. Give the patient adequate time to respond to your question, and listen to his response before you ask another question. Choose language that the patient can understand. Avoid using professional jargon that your patient is not familiar with. Also, consider the patient’s age and stage of development when asking a question. Adjust your communication strategies and techniques when interviewing children, elderly patients, patients with special needs, and patients from different cultures. Take notes so that you can remember the information the patient provides to you. Different types of questions promote different responses from your patient.

- **Open-ended questions.** Questions that allow the patient to give a detailed response in his own words are called open-ended questions. This form of questioning will provide you with the most information. For example, when you arrive on scene you need to obtain the patient’s chief complaint. If you ask “What seems to be the problem?” it allows the patient to state his chief complaint in his own way. “How are you feeling?” is another open-ended question that will provide significant information about your patient’s condition. Keep in mind that some patients may not be able to provide a lot of detail because of their physical or emotional state during the emergency. If possible, however, ask open-ended questions throughout the patient interview.

- **Closed-ended questions.** Questions that call for specific information from the patient are called closed-ended questions, or direct questions. These types of questions are helpful when you need to get information quickly or to obtain additional information that may not have been provided from an open-ended response. They can be used to direct and control the flow of the interview. “What medications do you take?” and “When did the pain begin?” are examples of closed questions. The patient will normally respond with only the information you have asked for. These questions are usually easier for the patient to answer. Many of the questions that you ask during your history taking will be closed questions.

For more about questioning and history taking, see Chapter 13, “Patient Assessment.”

**Considerations in Interviewing**

It is important to keep the patient interview moving in a therapeutic direction. Some considerations to keep in mind when you are interviewing the patient include the following:

- **Do not ask leading or biased questions.** Leading questions are questions that suggest an answer guided by the individual who is asking the question. An example of a leading question would be “So you’re having chest pain. It really hurts badly doesn’t it?” This type of question promotes answers that may not be accurate or beneficial to the patient interview and may lead the EMT to ask a series of questions that may not relate to the patient’s actual complaint or symptoms.

- **Do not interrupt your patient when she is speaking.** You cannot listen or communicate effectively if you are not paying attention to what your patient is saying or doing. You may miss pertinent information that could affect your patient care if you do not allow the patient to finish her thoughts (Figure 5-12).

- **The patient or the EMT may talk too much.** When a patient is overly talkative, one way to help the interview progress is to ask more closed questions. This will
help keep the answers shorter while still providing useful information. If you are overly talkative, you will not be able to actively listen to what your patient has to say.

- **Do not provide false assurance.** Never lie to your patient. Be honest but not heartless. Remember that most patients are overwhelmed by the emotions and situation they are enduring and look to you for safety, empathy, and assurance. If you genuinely address their concerns, they will typically feel more at ease.

- **Do not give inappropriate advice.** As a medical professional, you will be asked for advice by your patients. They want to have answers about their condition, but the best advice you can give them is to be evaluated by a physician at the hospital. You should not offer any form of diagnosis of your patient’s condition, nor should you discourage your patient from receiving prompt medical treatment. Remember that you are an authority figure, and your opinion matters to your patients. Do not overstep or abuse the trust they have placed in you.

- **Do not ask “why” questions that imply blame.** Remain impartial and nonjudgmental at all times. Remember that your primary concern is for your patient. By asking questions like “Why did you do that?” you are creating an intimidating atmosphere that will impede both your communication and your patient care.

- **Family preference issues.** Although most family members are trying to help the patient, it is important to know your department’s policies about interacting with family. Adults who are capable of providing their own informed consent are entitled to make their own decisions, regardless of their families’ preferences. Explain the patient’s rights to the family in an empathetic way. However, it is necessary to consider the families’ preferences when treating and transporting children who require parental consent. Similarly, if the patient is mentally incompetent or is incapable of providing informed consent for any other reason, family preferences should be considered and honored if possible. (See Chapter 3, “Medical, Legal, and Ethical Issues,” for a more detailed discussion of consent.) If, for whatever reason, the patient’s situation dictates the use of a facility that is not preferred by the family or patient, explain kindly to the family why the facility you suggest is necessary. For example, if you have a major trauma patient but the family requests that you take the patient to a small local community emergency department, you can explain that the facility they want to go to may not have the staff or equipment to properly care for their loved one’s injuries. Most patients and family members will be responsive to the change if you explain why it is in the patient’s best interest.

- **Motivating the unmotivated patient to talk.** Start the interview in the normal way. Attempt to use open-ended questions to gain pertinent information. Make sure the patient understands the questions you are asking. Reassure him that you are there to help him. If your patient speaks a different language, you may choose to use a language line, which is an interpreter service provided by telephone. If the patient still has difficulty or refuses to answer your open-ended questions, ask closed questions instead. Provide positive feedback to any answers you receive and continue to build rapport. Continue to ask questions your patient can understand and continue to provide positive feedback to him. If your patient has any special needs, make sure you address them appropriately.

- **Interviewing a hostile patient.** Sometimes you must interview a patient who is hostile and does not want your help. Some patients may be under the influence of street drugs or alcohol while others may have psychological or other behavioral issues. Remember that if your safety is compromised, you must not approach the patient until the scene is safe. (See Chapter 12, “Scene Size-up.”) Request help from law enforcement if necessary. Some patients may require restraint. If they do, know your department’s protocols and policies. It may also be necessary for you to have additional personnel available with you in case the patient becomes violent or makes false accusations. Once the scene is secured and safe, begin the interview as usual. To overcome some of the hostility, try to establish a good rapport with the patient. Make sure that you maintain a professional nonthreatening demeanor. Advise the patient that you are there to help him, and explain the benefits of having his cooperation. Inform your patient what conduct and behaviors are acceptable, and provide him with alternative ways to express himself. Then, conduct the interview in the same way that you would for any other unmotivated patient.

## Special Circumstances

There are some categories of patients with whom you will have to make extra efforts to establish effective communications (Figure 5-13). You must adjust your
communication strategies to meet the needs of your patients. Remember that, even when you are having problems communicating with someone, you should remain calm, confident, and caring. The following sections describe special communication circumstances that should be addressed by the EMT.

Transcultural Considerations

When providing care to a patient, the EMT should consider how the patient's culture will influence the dynamics of the call. Culture is composed of the thoughts, communications, actions, and values of a racial, ethnic, religious, or social group. It impacts how information is received, how illness is viewed, and what treatments are preferred by the individual patient. It is important to understand that both the EMT and the patient bring cultural stereotypes to a professional relationship. These stereotypes must be overcome to achieve a therapeutic relationship. Ethnocentrism is the view that one culture's way of doing things is the right way and any other way is inferior. EMTs should not view any culture as superior to another. It is important for the EMT to respect the patient's culture and avoid any cultural imposition. You should never impose your beliefs or values on your patients.

When addressing a patient from a different culture, you should begin by introducing yourself as you want to be called. Pay careful attention to the space between yourself and the patient. Remember that various cultures view space differently. Be sure to watch your patient for nonverbal signs that you are or are not maintaining an appropriate amount of space between you. In other cultures, many people accept the role of the sick person in different ways. Some of your patients may use established folk medicine practices before calling for your assistance.

Some patients may not speak English, and you may not speak their language, thus creating a language barrier between you and them. You can ask if relatives or bystanders can interpret for you. If no one at the scene can assist, check with dispatch or medical direction to see if they have anyone who can interpret for you over the radio. Toll-free interpreter lines are available. Remember to consider who has interpreted the information for you.

Considerations for Elderly Patients

Be prepared to take extra time in communicating with elderly people. Aging can bring with it potential problems with hearing and vision. Do not assume that all elderly patients have such problems, but if you detect signs of them, show understanding. Speak slowly, distinctly, and more loudly to such patients. Obtain their glasses or hearing aids for them. This will help in building a good rapport and communicating more effectively.

When dealing with a person who has a hearing problem, be sure your lips are visible as you speak. Make sure that you speak clearly, slowly, and distinctly. If a patient is deaf but indicates he can communicate through American Sign Language (ASL), check to see if relatives or bystanders can interpret for you. Also consider writing notes on a pad to communicate.

Never appear brusque or impatient, especially when helping an elderly patient. Always listen to the patient and allow ample time to answer your questions. Elderly patients may require extra assistance in collecting valuable information or their medications at the scene. Remember that these patients may easily become tired, and offer to help them get what you need for them. Many elderly patients resent being talked to as if they are children or mentally incapacitated. Make sure that you treat elderly patients, as you do for all patients, with respect and compassion and without condescension.

Considerations for Children

Working with children requires extra patience and effort. Having a child's parents present can aid in communicating with the child, but be sure the parents understand that they should remain calm and confident in front of the child. If they seem too frightened or disoriented by the situation, they will communicate those feelings to the child. Many elderly patients resent being talked to as if they are children or mentally incapacitated. Make sure that you treat elderly patients, as you do for all patients, with respect and compassion and without condescension.

SUMMARY

Communication is one of the most fundamental functions performed in emergency medical services and is involved in all phases of a call. The call is initiated by communication between the patient, a relative, or a bystander, and the call taker. You are then notified by either verbal or digital communication to respond to the scene. At the scene and at the receiving facility, you will communicate with members of your team and with other health care professionals.

Communication during patient assessment and care is a primary means for gathering information from and about the patient and for providing appropriate emergency care to the patient. It should be performed in a manner that achieves a positive relationship with the patient and that will benefit the patient’s outcome. You can adjust your communication strategies to develop a good rapport and facilitate communication with the broad variety of patients that you will encounter.

You will provide a verbal report to the receiving medical facility over the radio and finally in person. As communication systems continue to become more technologically sophisticated, you must refine your communication practices to meet the needs of the system.

Case Study Follow-up

Scene Size-up

You have been dispatched to 101 Bate Road with a report of a man bleeding. You approach the scene carefully, looking for any signs of danger. You see nothing that causes you concern, but you still exercise caution as you and your partner don gloves and protective eyewear and get out of the ambulance. As you do, a man who had been sitting next to the garage approaches you. He is holding a blood-soaked rag around his right hand. His shirt and pants are also bloodstained. The man appears pale and seems to be sweating a little.

As you start toward him, the man says, “You guys got here fast. I’m glad to see you. I feel like an idiot having to call, but no one else was home and I felt a little dizzy seeing all the blood. The bleeding’s almost stopped now, though. Oh, yeah. Hi. I’m Dave Behrens.”

You introduce yourselves and lead Mr. Behrens to the ambulance where he can sit down. When he’s seated, you ask, “How did you injure yourself, Mr. Behrens?” He replies, “I was cutting some molding with my saber saw at my workbench. That’s in the garage. I think the cat must have gotten in and knocked over a bottle. Anyway, it startled me. I turned to look and ran my hand into the blade. Idiot.”

Primary Assessment

Your general impression of the patient is of a male in his mid-40s, injured, and alert. Because he responds fully to all questions, you see he has no breathing problems and his airway is patent. You assess his radial pulse on the uninjured side and find it to be slightly fast, but strong. The rag wrapped around the hand he says he injured is blood soaked, but no blood appears to be dripping from the wrapping now. Because the bleeding appears to be controlled and Mr. Behrens displays no signs of shock, he is not considered a priority for rapid transport.

Secondary Assessment

Mr. Behrens has already given you the mechanism of injury, a cut from the blade of a saber saw. You now expose the injury, carefully removing the greasy rag in which he has wrapped the hand. The injury is an approximately 3-inch-long laceration across the base of the palm. The wound is now bleeding only minimally. You apply a sterile dressing to the wound and bandage it in place.

You assess distal perfusion by observing skin color, which appears normal, and by feeling the injured hand, which is warm and moist. You ask Mr. Behrens if he can gently wiggle the fingers of the injured hand and he does so. You then ask him to turn his head to one side and identify the fingers on the injured hand that you touch. He does so successfully.

You and your partner obtain a set of baseline vital signs. Mr. Behrens’s blood pressure is 148/86 mmHg. His heart rate is 92 per minute. His respirations are 14 per minute, full and adequate. His skin is normal color, warm, and moist.

You take a history. It reveals the following: Mr. Behrens says the wound is causing slight pain; he has an allergy to penicillin; he is not currently taking any medications; he denies having any significant medical problems; he had a cup of coffee about 15 minutes before cutting himself; he denies that there were any strange or unusual problems prior to the accident.

You explain to Mr. Behrens that a doctor should look at and treat the cut and that you will transport him to the hospital. He refuses, however, to ride on the cot, saying, “It’s bad enough that I had to call you for a dumb mistake. continued
I’m not going to go in like something from *ER.*” He agrees to ride on the jump seat and you secure him to it.

As you start off, you radio in a report: “Dispatch, this is Unit 2. We are en route to Columbia Memorial Hospital with a nonpriority patient.” Dispatch replies, “Unit 2 en route to Columbia Memorial at 1143 hours.”

**Reassessment**

Your partner is riding in the back with Mr. Behrens. She performs the reassessment. She finds that Mr. Behrens remains completely alert and oriented. Blood has not soaked through the dressing, an indication that bleeding has been controlled. She takes another set of vital signs, then radios ahead to the hospital: “Columbia Memorial, this is Craryville BLS Unit 2 en route to you with an ETA of 10 minutes. We have a 46-year-old male with a 3-inch laceration of the right hand caused by a saber saw. Mr. Behrens is allergic to penicillin. We applied a dressing and bandages to the wound and the bleeding appears to have stopped completely. His vitals are blood pressure 144/82 mmHg, pulse 80 bpm, respirations 14 per minute, skin color, temperature, and condition are normal.”

The nurse takes charge of Mr. Behrens while your partner fills out the prehospital care report. You begin to straighten and clean the back of the ambulance. When your partner returns, you radio, “Dispatch, this is Unit 2. We are available for assignment.” Dispatch replies, “Unit 2 available for assignment at 1207 hours.” You then start back to base, remembering that you will radio dispatch upon your arrival there.

**IN REVIEW**

1. List the standard components of an EMS communications system.

2. Explain the function of a repeater.

3. Explain legal considerations that apply to EMS communications.

4. List the points at which EMTs on a run are expected to communicate with dispatch.

5. Explain the procedure that should be followed when medical direction orders an EMT to administer a medication or follow a designated procedure with a patient.

6. List the information that the EMT should provide to the receiving facility while en route with the patient.

7. List the information the EMT is expected to provide in the oral report when turning a patient over at a receiving facility.

8. Explain the importance of eye contact with a patient.

9. Explain the possible effects on communication with a patient of (a) the EMT’s body position and (b) touch.

10. Explain what measures an EMT might take when trying to communicate with a patient who is deaf or hearing impaired.

11. Explain the process of communication.

12. Identify special interview situations that require communication adjustments.

13. Explain how culture can influence communication.

14. List hazards associated with interviewing patients.

15. Describe how to use questions to obtain specific information from a patient.

16. List possible types of responses that are common in communication.

17. Describe how to build a good rapport with a patient.
CRITICAL THINKING

You arrive on the scene and find a 36-year-old female patient who complains of severe abdominal pain. The patient is alert and oriented. Her vital signs are BP 88/64 mmHg; HR 128 bpm; R 24 and adequate chest rise; skin is pale, cool, and clammy; SpO₂ is 96% on room air. Her radial pulses are weak. She states the pain began suddenly about 4 hours ago and has progressively worsened. She was sitting on the couch watching television when it began. Nothing makes the pain better or worse. The pain is dull and aching, and it is intermittent. The pain does not radiate.

The patient rates the severity of her pain as 8 on a scale of 1 to 10. She states she feels light-headed and dizzy every time she stands up, and she also feels nauseated. She has no known allergies and takes over-the-counter Prilosec for heartburn. She has no pertinent medical history. She reports she had her tonsils removed when she was 10 years old. She has had nothing to eat or drink for about 7 hours. She states that she has "not felt real good" for a few days, and other than the time she has spent working at her desk at work, she has been at home on the couch. Her pupils are equal and sluggish to respond. She has no JVD. Her breath sounds are equal and clear bilaterally. Her abdomen is rigid and tender. There is no evidence of trauma to the abdomen. She has good motor and sensory function in all four extremities. Her peripheral pulses are very weak.

En route to the hospital, the patient begins to close her eyes. You must verbally instruct her to open her eyes. Her BP is 82/62 mmHg, HR 134 bpm, and R 26 with adequate chest rise. The pulse oximeter is providing an "error" reading. Her skin is more pale, cool, and clammy and her radial pulses are barely palpable. Your estimated time of arrival at the hospital is 7 minutes.

1. What techniques would you use to communicate with this patient?
2. Are there any special circumstances that you would consider when communicating with this patient?
3. Would you contact medical direction during your management of this patient?
4. What information is important to relay in the radio report to the receiving medical facility?
5. What information would you provide in your oral report to the medical personnel at the receiving medical facility during the transfer of care?
6. What information would you report regarding the change in the patient’s condition?
Lifting and Moving Patients

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Preparatory** (Content Areas: Workforce Safety and Wellness)

**COMPETENCY •** Applies fundamental knowledge of the EMS system, safety/well-being of the EMT, medical/legal and ethical issues to the provision of emergency care.

**OBJECTIVES •** After reading this chapter, you should be able to:

6-1. Define key terms introduced in this chapter.
6-2. Explain the importance of always using proper techniques when lifting, carrying, and moving patients and equipment.
6-3. Define the term body mechanics.
6-4. Demonstrate each of the four principles of body mechanics listed in the text when lifting and moving patients and equipment.
6-5. Explain the roles of proper body posture and physical fitness in preventing injuries resulting from lifting and moving patients.
6-6. Describe considerations in teamwork and communication with partners and patients when lifting and moving patients.
6-7. Apply the general guidelines for lifting and moving patients that are described in the text.
6-8. Discuss the advantages, disadvantages, and steps of each of the following lifting and moving techniques and processes:
   a. Power lift
   b. Power grip
   c. Squat lift
   d. One-handed equipment carrying
   e. Reaching
   f. Log roll
   g. Pushing and pulling
6-9. Differentiate between scenarios in which emergency, urgent, and nonurgent moves are indicated.
6-10. Given a scenario, demonstrate an appropriate moving technique to be used, including:
   a. Armpit-forearm drag
   b. Shirt drag
   c. Blanket drag
   d. Rapid extrication
   e. Direct ground lift
   f. Extremity lift
   g. Direct carry
   h. Draw sheet method
6-11. Demonstrate the steps required to securely “package” a patient for transport.
6-12. Describe the proper use, advantages, disadvantages, and limitations of each of the following pieces of equipment used in lifting and moving patients:
   a. Wheeled stretcher
   b. Portable stretcher
   c. Stair chair
   d. Backboard
   e. Scoop stretcher
   f. Basket stretcher
   g. Flexible stretcher
   h. Devices for bariatric patients
6-13. Given a scenario involving any of the following types of patients, demonstrate proper positioning of the patient:
   a. Unresponsive patient
   b. Patient with chest pain or difficulty breathing
   c. Patient with known or suspected spinal injury
   d. Patient in shock
   e. Patient with nausea or vomiting
   f. Patient in third trimester of pregnancy
   g. Infant or toddler
   h. Elderly patient
   i. Patient with a physical disability
6-14. Discuss special considerations when preparing patients for air medical transport.
6-15. Discuss special considerations when using a neonatal isolette.
**INTRODUCTION**

A key skill that you will perform with almost every patient contact is the lifting and/or moving of a patient from where he is to your cot, then to the ambulance, and eventually to the hospital cot. Unfortunately, too many EMTs are injured every year because they attempt to lift patients or equipment improperly. The knowledge and use of proper body mechanics are a necessary foundation for your health, longevity, and effectiveness as an EMT.

The best way to move a patient in any circumstance is generally the easiest way that will not cause injury or pain to your patient or to yourself. Let your equipment do the work whenever possible. If you must lift, do it with a device designed for that purpose, if possible. As a rule, get as much help as you can to carry patients and equipment. Never risk falling or injuring yourself. And always follow the rules of body mechanics.

**Body Mechanics for Safe Lifting**

As an EMT you are required to lift and carry patients and heavy equipment. If you perform these tasks improperly, bodily injury, strain, and lifelong pain can be the result. With conscious planning, good health, and skill, you can perform these tasks with minimum risk to yourself. Apply the principles and techniques of proper lifting and moving every day. Practice often enough for them to become automatic. Make them a habit that increases your safety and performance—even in the most stressful emergency situations.

**Four Basic Principles**

**Body mechanics** are defined as the safest and most efficient methods of using your body to gain a mechanical advantage. They are based on four simple principles:

- **• Keep the weight of the object as close to the body as possible** (Figure 6-1 ■). Back injury is much more likely to occur while reaching a great distance to lift a light object than while reaching a short distance to lift a heavy object.

- **• To move a heavy object use the leg, hip, and gluteal (buttocks) muscles plus contracted abdominal muscles.** The use of these muscles will help you generate a huge amount of power safely. Always avoid using back muscles to move a heavy object.

- **• “Stack.”** Visualize the shoulders stacked on top of the hips, and the hips stacked on top of the feet (base). Then move them as a unit. If any of the three are not aligned with the others, you can create twisting forces that are potentially harmful to the lower back.

- **• Reduce the height or distance through which the object must be moved.** Get closer to the object or reposition it before lifting (Figure 6-2 ■). Lift in stages if necessary.

---

**Case Study**

**The Dispatch**
EMS Unit 101—proceed to 605 Lindsey Drive in Rockaway—a 72-year-old patient has a routine transfer to Dover General—time out is 0910 hours.

**Upon Arrival**
You are a probationary EMT accompanied by a training officer and an experienced EMT. Your training officer tells you that she knows the patient, Amanda Sanchez, and that this is one of three prescheduled visits Mrs. Sanchez takes to the hospital dialysis center every week. She tells you the patient cannot walk without assistance and will need help getting down one flight of stairs. As your partner parks the ambulance, he remarks that there is still snow and probably ice on the walk to the house.

**How would you proceed to package and transport this patient?**
*During this chapter, you will read about how to lift and move patients using good body mechanics and equipment designed to assist in patient movement. Later, we will return to the case study and apply the procedures learned.*
One extreme of poor posture is the swayback, or excessive lordosis. In this posture the stomach is too anterior and the buttocks are too posterior, causing excessive stress on the lumbar region of the back. Another extreme is the slouch, or excessive kyphosis. In this posture the shoulders are rolled forward, which results in fatigue of the lower back and increases pressure on every region of the spine (Figure 6-3).

Be aware of your posture. While standing, your ears, shoulders, and hips should be in vertical alignment, with knees slightly bent and pelvis slightly tucked forward (Figure 6-4). In the proper sitting position, your weight should be evenly distributed on both ischia (lower portion of the pelvic bones), with your ears, shoulders, and hips in vertical alignment, and your feet should be flat on the floor or crossed at your ankles. If possible, your lower back should be in contact with the support of the chair (Figure 6-5).

Proper body mechanics cannot sufficiently protect you if you are not physically fit. A proactive, well-balanced physical fitness program should include flexibility training, cardiovascular conditioning, strength training, and nutrition. Such a program can help you prevent injury, enhance performance, and manage stress.

Posture and Fitness

One much-overlooked aspect of proper body mechanics is posture. Because you will spend a great deal of time sitting or standing, poor posture can easily fatigue back and abdominal muscles, thereby making you vulnerable to back injury.

Communication and Teamwork

In an emergency, teamwork and effective communication among team members are essential. Patients come
in all sizes, shapes, and strengths. Just as a football coach positions players according to their abilities, rescuers should capitalize on their abilities to ensure the best outcome in an emergency.

All team members should be trained in the proper techniques. Problems can occur when partners are greatly mismatched, and not only to the overloaded weaker partner. The stronger partner can also be injured if the weaker one fails to lift. Ideally, partners in lifting and moving a patient or object should have adequate and equal strength and height. Two adequately strong but weaker rescuers are as efficient and safe as the pairing of two stronger rescuers.

In order for team members to work together effectively, they need to communicate throughout all lifting and moving tasks. Use commands that are easy for team members to understand. Verbally coordinate each lift from beginning to end. Good teamwork will also allow you to:

- Size up the scene immediately and accurately.
- Consider the weight of the patient and recognize the need for additional help.
- Be aware of the physical abilities and limitations of each team member.
- Select the most appropriate equipment for the job.

Just as important as the communication between team members is the EMT’s communication with the patient. If startled or frightened, the patient might shift body weight while you attempt the lift. Shifts in weight can cause disabling injury to rescuers as well as cause significant additional injury to the patient. Whenever a patient is able to understand, explain the plan before any action is taken. This will improve patient confidence and can engage the patient in assisting in his own rescue.

### GENERAL GUIDELINES FOR LIFTING AND MOVING

Know your own physical abilities and limitations. Do not overestimate yourself or other rescuers. Before lifting, know or find out the weight of the patient as well as the weight limitations of the equipment being used. Call for additional help whenever necessary. Even though your first impulse may be to jump in and help the patient, you must not proceed until you know you can do so safely.

Always try to use an even number of rescuers to maintain balance. Two-rescuer teams should carry heavy loads for 1 minute or less. More time can generate a high level of muscle fatigue, which can significantly increase the potential for injury. Whenever possible, transport patients and equipment on wheeled stretchers or other rolling devices.

When you must carry, keep the weight as close to your body as possible. Keep your back in a locked-in
position. Do not hyperextend your back, or lean back from the waist. Refrain from twisting, and never lift and twist simultaneously. First lift, then turn as a unit.

**The Power Lift**

The power lift is the technique that offers you the best defense against injury and protects the patient with a safe and stable move. It also is a useful technique for rescuers with weak knees or thighs. In performing this technique, keep your back locked and avoid bending at the waist. Follow these steps (EMT Skills 6-1):

1. Place your feet a comfortable distance apart. For the average-sized person, this is usually about shoulder width. Taller rescuers might prefer a little wider stance since this brings them closer to the object to be lifted.
2. Turn your feet slightly outward. Most people find that this helps them feel more comfortable and more stable.
3. Bend your knees to bring your center of gravity closer to the object to be lifted. As you bend your knees, you should feel as though you are sitting down, not falling forward.
4. Tighten the muscles of your back and abdomen to splint the vulnerable lower back. The back should remain as straight as comfortable (there is normally a slight inward curve), with your head facing forward in a neutral position.
5. Straddle the object. Keep your feet flat with your weight evenly distributed and just forward of the heels.
6. Place your hands a comfortable distance from each other to provide balance to the object as it is lifted. This is usually at least 10 inches apart.
7. Always use a power grip to get maximum force from the hands (Figure 6-6). That is, your palm and fingers should come in complete contact with the object and fingers should be bent at the same angle.

8. As lifting begins, your back should remain locked in as the force is driven through the heels and arches of your feet. Your upper body should come up before the hips.

9. Reverse these steps to lower the wheeled stretcher or other object.

**The Squat Lift**

The squat lift is an alternative technique you can use if you have one weak leg, one weak ankle, or if both your knees and legs are strong and healthy (Figure 6-7). In performing this technique, avoid bending at the waist.

1. Place your weaker leg slightly forward. This foot should stay flat on the ground throughout the lift.
2. Squat down until you can grasp the cot, stretcher, or other patient-moving device. Be sure to use the power grip.
3. Push yourself up with your stronger leg. Make sure your back is locked and your upper body goes up before your hips. Lead with your head.

While performing any lift, always remember to use your leg muscles—not your back—to lift, keep the weight as close to your body as possible, position yourself correctly, and communicate clearly and frequently with your partner.

**One-Handed Equipment-Carrying Technique**

There are times when you will want to lift and carry certain equipment with one hand. When you do, be sure to keep your back in a locked position. Maintain proper body mechanics and avoid leaning to the opposite side too much to compensate for the imbalance.

To use a one-handed carrying technique (Figure 6-8) to lift and move a patient-carrying device, first stagger...
When pushing, push from the areas between your waist and shoulders, if possible. If the weight is below waist level, use the kneeling position to avoid bending. Keep your elbows bent, with your arms close to the sides of your body. This will help to increase the force you can apply. Due to the inherent danger, even likelihood, of injury, avoid pushing or pulling an object that is overhead.

LIFTING AND MOVING PATIENTS

As mentioned at the beginning of the chapter, the principles of proper body mechanics and lifting techniques must be applied to all situations in which the EMT has to lift patients or move equipment. Although these principles are not expressly stated in the following discussions of specific lifting and moving techniques, it is expected that you, as an EMT, will always recall the principles of body mechanics to ensure your own safety and that of your partners and patients. Maintain a straight, rigid back by contracting the abdominal and gluteal muscles. Bend at the hips, not at the waist. Keep your head in a neutral position, not flexed forward or extended backward, and use your leg muscles, not your back, to lift, move, or drag the patient (Table 6-1).

There are three categories of patient moves: an emergency move, an urgent move, and a nonurgent move. In general, an emergency move should be performed when there is immediate danger to the patient or to the rescuer. An urgent move is performed when the patient is suffering an immediate threat to life and the patient must be moved quickly and transported for care. Finally, a nonurgent move is one in which no immediate threat to life exists and the patient can be moved in a normal manner when ready for transport.

Emergency Moves

The top priority in emergency care is to maintain the patient’s airway, breathing, and circulation. The rule of
Inability to provide lifesaving care because of the patient’s location or position. There will be times when you need to change a patient’s position, for instance to control hemorrhage, to defibrillate, or to perform CPR.

Remember: The greatest danger to the patient in any emergency move is the possibility of aggravating a spinal injury. Yet, it is impossible to move a patient quickly and still provide as much protection to the spine as would a spine board. In every such emergency, however, make every effort to provide as much protection to the spine as possible. And always make sure you pull the patient in the direction of the long axis of the body.

Three types of emergency moves are the armpit-forearm drag, the shirt drag, and the blanket drag.

The Armpit-Forearm Drag
In general, if the patient is on the floor or ground, you can move him by inserting your hands under the patient’s armpits from the back. Grasp the patient’s left forearm with your right hand, the right forearm with your left hand, and drag. Make sure you pull the patient in the direction of the long axis of the body (Figure 6-10).

The Shirt Drag
If the patient is wearing a shirt, you can use it to support the patient’s head and pull (Figure 6-11). Note that the shirt drag cannot be used if the patient is wearing only a T-shirt.

1. Fasten the patient’s hands or wrists loosely together. If possible, link them to a belt or pants with a small velcro strap or self-adherent bandage. This will serve to prevent the patient’s arms from flopping or slipping out of the shirt.
2. Grasp the neck and shoulders of the shirt so that the patient’s head rests on your fists.

thumb is to control any life-threatening problems and stabilize the patient before moving him. However, when the scene of an accident is unstable, or threatening to your life and the patient’s, your priority changes. You must move the patient first. Make an emergency move only when no other options are available. Follow local protocol. Always take appropriate precautions to be sure you do not become an additional victim of the emergency.

In general, an emergency move should be performed when there is immediate danger to the patient or to the rescuer. Consider an emergency move under the following conditions:

- **Immediate environmental danger to the patient or rescuer,** such as:
  - **Fire or danger of fire.** Fire should always be considered a grave threat, not only to patients, but also to rescuers.
  - **Exposure to explosives or other hazardous materials.** When a patient is directly exposed to substances that can cause grave injury or death, move the patient immediately.
  - **Inability to protect the patient from other hazards at the scene.** Move the patient to safety when, for example, you haven’t the resources to protect him from uncontrolled traffic, physically unstable surroundings, extreme weather conditions, or hostile crowds.
  - **Inability to gain access to other patients who need lifesaving care.** In cases where more than one patient has been injured, you may need to move one in order to gain access to another. This may apply to moving a moderately injured person in order to gain access to one who has life-threatening injuries.

- **Use teamwork, equipment, and imagination to make sure you are always in the position of using proper body mechanics.**
- **Use the power lift and power grip techniques as a best defense against injury.**
- **Reduce the height or distance through which an object must be moved.** Lift in stages if necessary.
- **Lift an object as close to your body as possible to avoid back injury.**
- **Avoid using back muscles to lift.**
- **Use legs, hips, and gluteal muscles plus abdominal muscles for safe, powerful lifts.**
- **While you are carrying an object, keep shoulders, hips, and feet in alignment.**
- **Use the proper posture—ears, shoulders, and hips in vertical alignment—when standing and sitting.**
- **Improve personal physical fitness to build strength and manage stress.**

Three types of emergency moves are the armpit-forearm drag, the shirt drag, and the blanket drag.

Many times a patient in a motor vehicle collision must be quickly removed from the vehicle for emergency care and immediate transport, and the application of a short spine board or vest to immobilize the spine would take too much time. The rapid extrication move is designed for this situation. Medical patients may also require an urgent move. A patient in cardiac arrest who is found lying on the couch would need to immediately be placed on the floor or a hard surface to effectively carry out resuscitation.

**Rapid Extrication**

Rapid extrication should be used in patients with any abnormality of the airway, breathing, oxygenation, or circulation and for those with critical injuries and illnesses. See Chapter 32, “Spinal Column and Spinal Cord Trauma,” for detailed discussion and illustrations of rapid extrication.

Indications for an urgent move using the rapid extrication technique include but are not limited to the following:

- Altered mental status
- Inadequate respiratory rate or tidal volume
- Indications of shock (altered mental status; pale, cool, clammy skin; tachycardia; increased respiratory rate)
- Injuries to the head, neck, chest, abdomen, pelvis
- Fracture of both femurs
- Major bleeding

A summary of the rapid extrication procedure from a motor vehicle follows:

1. One rescuer should bring the patient's head into a neutral in-line position and provide manual stabilization. This is best achieved from behind or to the side of the patient.
2. A second rescuer should apply a cervical-spine immobilization collar as a third places a long backboard near the door. The third rescuer should then move to the passenger seat.
3. The second rescuer should support the patient’s thorax as the third frees the patient’s legs from the pedals or from under the dashboard.
4. The second and the third rescuer rotate the patient in several short, coordinated moves until the patient’s back is in the open doorway and his feet are on the seat.
5. Since the first rescuer can no longer support the patient’s head, another rescuer should support the head until the first rescuer exits the vehicle and takes over supporting the head from the door opening.
6. The end of the long backboard is placed on the seat next to the patient’s buttocks. Assistants support the other end of the board as the first and second rescuers lower the patient onto it, the first maintaining in-line stabilization of the head and neck.
The second and third rescuers should then slide the patient into the proper position on the board in short, coordinated moves as the first continues manual stabilization.

Several variations of this technique are possible. The most critical factor is that this procedure must be accomplished rapidly, but without any compromise to the patient’s spine. In addition, operating inside a vehicle places the rescuer's lower back in a vulnerable position. Whenever possible, you should support your weight with a free arm or by resting your chest against the seat backs.

**Nonurgent Moves**

When there is no immediate threat to life, take the time to choose the best equipment and positioning for moving the patient safely. Generally, the best way to move a patient is the easiest way that will not cause injury or pain. That includes “walking” the patient, if he is able, while supporting him. Never walk a patient who becomes light-headed or sweaty upon standing or who is having chest pain or respiratory problems, has an injured lower extremity, or has suspected spinal injury.

Whenever you move, lift, or carry a patient, remember to move him as a unit. Keep the patient’s head and neck in a neutral position. If you suspect head, neck, or spinal injury, take all necessary spinal precautions. Be sure that all rescuers understand what is to be done before any move is attempted, and make one rescuer responsible for giving commands.

There are many ways to move patients. You are only limited by your imagination and the basic principles of body mechanics and patient safety and comfort. The direct ground lift, extremity lift, direct carry, and draw sheet methods are accepted nonurgent moves that provide the greatest safety to both you and the patient.

**Direct Ground Lift**

Note that the direct ground lift is not recommended for a heavier patient. When lifting a patient from the ground, it is usually safer and more mechanically efficient to use a long backboard. However, when this cannot be accomplished, follow these steps (EMT Skills 6-2):

1. Two or three rescuers should line up on the same side of the patient.
2. Each rescuer should kneel on one knee, preferably the same knee for all rescuers.
3. The second rescuer should place the patient's arms on the chest, if possible.
4. The first rescuer should then cradle the patient's head by placing one arm under the patient's neck and shoulder. Then he should place his other arm under the patient's lower back.

5. The second rescuer should place one arm under the patient's knees and one arm above the buttocks.
6. If a third rescuer is available, he should place both arms under the waist. The other two rescuers then should slide their arms either up to the midback or down to the buttocks as appropriate.
7. On signal from the first rescuer, they should lift the patient to their knees and roll the patient in toward their chests.
8. On signal from the first rescuer, they should stand and move the patient to the stretcher or other patient-carrying device.
9. To lower the patient, the steps are reversed.

Remember that you should bend at the hips and not at the waist, your back should remain straight, and the lifting force should be generated from your legs and buttocks, not the back.

**Extremity Lift**

Use the extremity lift to move a patient from the ground to a patient-carrying device (EMT Skills 6-3). Note that this lift should not be used on a patient with suspected spinal or extremity injuries.

1. The first rescuer should kneel at the patient's head. A second rescuer should kneel at the patient's side by the knees.
2. The first rescuer should place one hand under each of the patient’s shoulders, while the second rescuer grasps the patient’s wrists.
3. The first rescuer should slip his hands under the patient’s arms and grasp the patient’s wrists.
4. The second rescuer can then slip his hands under the patient’s knees.
5. Both rescuers should move up to a crouching position, keeping their backs straight and heads in neutral alignment.
6. On signal from the first rescuer, they should stand up simultaneously and move with the patient to a stretcher or other patient-carrying device.

While lifting the patient, each rescuer must maintain a straight back and contract the abdominal muscles. The rescuer’s head must remain in line with the back. (If the head were to be extended backward, the rescuer would be forced to use the lower back muscles. Flexing the head forward would also put undue force on the lumbar disks.) When lifting the patient, the rescuer should drive upward with leg and gluteal muscles.

**Direct Carry Method**

The direct carry is one way of transferring a supine patient from a bed to a wheeled stretcher or from any patient-carrying device to another (EMT Skills 6-4):
1. Position the wheeled stretcher perpendicular to the bed, with the head of the device at the foot of the bed.
2. Prepare the wheeled stretcher by unbuckling straps and removing other items. Both rescuers should stand between the bed and stretcher, facing the patient.
3. The first rescuer then slides an arm under the patient’s neck and cups the patient’s shoulder.
4. After the second rescuer slides a hand under the patient’s hip and lifts slightly, the first rescuer should slide an arm under the patient’s back. The second rescuer then places his arms under the patient’s hips and calves.
5. The rescuers slide the patient to the edge of the bed, lift and curl the patient to their chests, and then rotate and place the patient gently onto the wheeled stretcher.

**Draw Sheet Method**

Another way of transferring a supine patient from a bed to a wheeled stretcher or from any patient-carrying device to another is the draw sheet method (EMT Skills 6-5):

1. Loosen the bottom sheet of the bed.
2. Position the wheeled stretcher next to the bed. Prepare it by adjusting height, lowering rails, unbuckling straps, and so on.
3. Reach across the stretcher and grasp the sheet firmly at the patient’s head, chest, hips, and knees. As you reach across the stretcher, use your hips to support yourself against the stretcher.
4. Slide the patient gently onto the wheeled stretcher. Be sure to contract your abdominal and gluteal muscles to splint the lower back.

---

**Packaging for Transportation**

Packaging simply means readying the patient for transport. That is, once the patient is stabilized and all interventions have been checked, you must select and prepare the appropriate carrying device, safely transfer and secure the patient to the carrying device, and finally move the patient and carrying device to the ambulance for loading and unloading.

Some general considerations: Make sure the carrying device is locked in the open position before positioning the patient. Use an appropriate lifting, moving, or carrying technique to place the patient on the carrying device. Generally, place a sheet or blanket on the carrying device and, when the patient is positioned, cover him as appropriate with sheets or blankets to maintain body temperature. Then secure him with straps. Make certain all straps and ties are tucked in or positioned so that they will not cause you to trip and fall. When the patient is placed in the ambulance, be sure both the patient and the carrying device are secured properly before the ambulance moves.

**Note:** If you suspect head, neck, or spinal injury, take all necessary spinal precautions before, during, and after packaging.

**Equipment**

Both medical and trauma patients need to be moved, packaged, and transported in ways that will not make their conditions worse. To make the best choices of equipment for your patients, learn the advantages and disadvantages of each type (Table 6-2). Practice often, and follow manufacturer instructions for inspection, cleaning, repair, and upkeep.

**Wheeled Stretcher**

The wheeled stretcher (also called an ambulance gurney or cot) is the patient-carrying device most commonly used by rescue personnel (Figure 6-13). It is also the safest and most comfortable means of transferring a patient. Most wheeled stretchers are designed to accommodate weights up to 650 pounds and can be adapted to almost any patient position. They also can serve as a means of securing and carrying equipment to the patient’s location.

To roll a wheeled stretcher, the rescuer at the head pushes and the rescuer at the foot guides. One limitation of the device is that rolling is usually restricted to smooth terrain. However, four rescuers—one at each corner—can keep it stable and move it over rough ground. Two rescuers can carry a wheeled stretcher in narrow spaces. However, they would need to face each other from opposite ends, the stretcher could be easily unbalanced, and the lift and carry would require considerable strength (Figures 6-14a and 6-14b).

There are two basic types of wheeled stretchers in the United States: the lift-in cot and the roll-in cot (Figures 6-15a and 6-15b). Each weighs about

</tbody>
</table>
Trained emergency personnel should stay with a patient on a wheeled stretcher at all times. The patient should never be left unattended, even when secured. Before loading a wheeled stretcher into the ambulance, be sure there is enough lifting power. Load hanging stretchers before wheeled stretchers. Once in the ambulance, be sure the stretchers and patients are secure before the ambulance moves.

**Bariatric Stretchers and Devices**

With an ever-growing overweight population, specialized stretchers and other devices have been designed to transport morbidly obese patients. These stretchers and devices are called *bariatric devices* (EMT Skills 6-7). Some bariatric stretchers are designed to hold patients up to 1,600 pounds in a wheels-down position. The stretchers have larger wheels for stability, wider cot dimensions, and more heavily constructed frames. Some stretchers are part of a bariatric transport system that includes an
ambulance ramp and winch. There are even specialized bariatric transport ambulances now available.

**Portable Stretcher**

The portable ambulance stretcher is standard equipment (Figures 6-16a and 6-16b). It is usually made of a continuous tubular metal frame, canvas or coated fabric bottom, and straps to secure the patient. It may also be referred to as a soft cot. It is a conventional carrying device that is particularly useful when the patient must be removed from a space too confined or narrow for a wheeled stretcher. It is often used as an auxiliary to the wheeled stretcher when there is more than one patient to transport. It can be loaded easily into an ambulance and off-loaded easily once in the ambulance.

The portable ambulance stretcher generally is available in three styles: the basic model, the basic with folding wheels and posts, and the breakaway. The basic model is used as an auxiliary stretcher, which can be placed on the squad bench or suspended from hanging hardware inside the ambulance. It is very light and, though it has a load capacity of up to 350 pounds, it is not recommended for that much weight. Most models can be folded in half for storage.

One type of portable stretcher is the pole stretcher or canvas litter (Figure 6-16b), which has been used worldwide for centuries. It is lightweight and folds compactly. The vinyl-coated model is easy to clean. It is comfortable for the patient, especially when the head is padded, though it should not be used when spinal immobilization is necessary unless it is used with a long backboard. One drawback is that care must be taken when placing the patient on rocky ground for any length of time. Soft tissue injury may result. When you are going to use the canvas pole stretcher to transport a patient, take care to see that the crosspieces are locked in place. When lifting a patient on a pole stretcher, it is preferable to have four or more rescuers.

**Stair Chair**

A stair chair (Figure 6-17) is useful when a wheeled stretcher cannot traverse narrow corridors and doorways, small elevators, and stairways. Some models can be converted into portable stretchers. Do not use a stair chair when the patient has an altered mental status, suspected spinal injury, or injuries to the lower extremities.

To move a patient up or down stairs on a stair chair, explain to the patient everything you plan to do. Check to be sure all straps are secure. Then the rescuers should proceed with the following (EMT Skills 6-8):

1. One rescuer should stand behind the chair at the head, and another should stand at the foot facing the patient. A third rescuer, if available, should prepare to “spot” by standing behind the rescuer who will be moving backward (up or down the stairs). Instruct the patient not to reach out.
2. As the chair is tilted back by the rescuer at the head, the rescuer at the foot should grasp the chair by its legs.
3. Both rescuers should lift and begin to carry simultaneously. If the chair has wheels, they should not be allowed to touch the steps.
4. As the rescuers descend (or ascend) with the patient, the spotter should count out the steps and identify upcoming conditions.
Tracked Stair Chair. A newer model stair chair is also available and is designed with a track that can be lowered behind where the patient is sitting (Figure 6-18). This track comes into contact with the steps as the patient is being moved down stairs, and allows the chair to glide down the steps with minimal effort exerted by the EMT. It still requires two rescuers, one at the head and one at the foot of the patient, for stabilization of the device. While this style chair still has all the same features as more common models, the new design eliminates the need to lift the chair while moving down the steps.

Backboards
Standard operating equipment in any emergency vehicle is the backboard (Figure 6-19a). It can protect the patient from rocky ground surfaces, and it acts as a spinal immobilizer. Straps and a head immobilizer device usually can be applied and secured without problems.

Long and short backboards are made of lightweight plastic or composite materials with molded handholds. Common styles are the Farrington (rectangular with round corners) and the Ohio (with mitered corners and tapering sides). The Ohio fits into most basket stretchers and can be more easily maneuvered in and out of cars. Long backboards may also be referred to as long spineboards.

Short backboards usually are used to immobilize noncritical sitting patients before moving them. One special type of short backboard is the vest-type or corset-type immobilizer such as the Ferno Kendrick Extrication Device (KED) (Figure 6-19b). Once a short backboard is applied, the patient should be placed on a long backboard. See Chapter 32, “Spinal Column and Spinal Cord Trauma.”

Also available is a full body vacuum mattress that can be used as both a backboard and a moving device once the patient is placed on it (Figures 6-20a and 6-20b). This design uses vacuum technology to conform the mattress into whatever shape is necessary given the patient. It eliminates the need to pad any extra voids between a traditional rigid backboard and the patient’s body, and it becomes rigid enough after the vacuum has been applied to allow two or more EMTs to lift and carry the patient. Several benefits of this equipment are that it is lightweight, it conforms to the patient’s shape, it fits within a basket stretcher, and it is designed with several hand grips for the care providers to grasp when preparing to lift the patient.

Scoop Stretcher
Designed for patients weighing up to 300 pounds, the scoop or orthopedic stretcher is made to be assembled and disassembled around the patient (Figure 6-21). An advantage is that it can be used in confined areas where other conventional stretchers will not fit. It can also be used for pelvic fractures or bilateral femur fractures to prevent further injury. A disadvantage is that some devices are constructed entirely of metal, which picks up the temperature of the environment. Note also that the scoop stretcher is not recommended for patients with suspected spinal injury.
To use a scoop stretcher properly, you must have access to the patient from all sides. At least two rescuers are required—one to prepare and position the stretcher and one to move the patient. Follow these steps (EMT Skills 6-9):

1. Adjust the stretcher to the length of the patient.
2. Separate the stretcher halves, and place one on each side of the patient. Keeping the patient’s spine in-line, gently roll the patient onto one side. Slide half of the stretcher under the patient.
3. If you have not been able to examine the patient’s back before this time, do so now. Then return the patient to a supine position.
4. Assemble the head end of the scoop stretcher.
5. Roll the patient’s body to the other side. Swing the remaining half of the stretcher into a closed (assembled) position. Latch the foot end of the stretcher.
6. Pad the patient’s head and any bony prominence with a pillow or a folded sheet.
7. Secure the patient with at least three body straps.

**Basket Stretcher**

Most commonly called the Stokes basket, a basket stretcher is shaped like a long basket and comes in two basic styles (Figures 6-22a and 6-22b). One style has a welded metal frame fitted with a contoured chicken-wire web. The other style has a tubular aluminum frame riveted to a molded polyethylene shell. Either will accommodate a scoop stretcher or Ohio-type backboard. Basket stretchers will fit onto wheeled stretchers which can be used to move the patient. Be sure to secure the basket to the wheeled stretcher prior to any movement.
Flexible Stretcher

A flexible (or Reeves) stretcher is a special transfer device made of canvas or synthetic materials (Figure 6-23). It has six large lifting and carrying handles, three on each side. It is especially useful for narrow and restricted hallways such as those found in mobile homes. A patient on a backboard can be placed inside the flexible stretcher for moves down stairs or over rough terrain.

Patient Positioning

Generally, a patient is placed on a carrying device in a supine or sitting position, unless the patient’s condition dictates otherwise.

- **An unresponsive patient with no suspected head, neck, or spinal injury** should be placed in a left lateral recumbent position (coma or recovery position) to face the rescuer once in the ambulance. This position aids in draining fluids or vomitus from the mouth and helps prevent aspiration into the lungs.
- **A patient with chest pain or discomfort or with breathing difficulties** should be placed in a position of comfort, usually sitting up, if hypotension is not present.
- **A patient with suspected spinal injury** should be immobilized on a long backboard. Once immobilized, the patient and backboard can be tilted as a unit to place the patient on his left side for drainage from the mouth.
- **A patient in shock (hypoperfusion)** should be placed in a supine position unless your protocol indicates otherwise.
- **An alert patient who is nauseated or vomiting** should be transported in a sitting or a recovery position. That position should allow you to manage the patient’s airway.
- **A pregnant patient in her third trimester** should be positioned on her left side.

Consider the following suggestions when moving and positioning patients with special needs:

- **Pregnant women.** A pregnant woman will probably feel more comfortable on her left side. That position takes the weight of the baby off the large blood vessels and nerves in the abdomen, preventing supine hypotensive syndrome (dizziness, drop in blood pressure, and decreased cardiac output). If there is excess vaginal bleeding, place the woman in a supine position. If you suspect a prolapsed umbilical cord, place the woman on her back and elevate her hips with a pillow. Follow local protocol. (See Chapter 37, “Obstetrics and Care of the Newborn,” for details on these conditions.)
- **Infants and toddlers.** An infant or toddler who is not critically injured can usually be carried easily in an infant car seat. When possible, use the child’s own car seat to reduce fear of being in an unfamiliar environment. You can also use the car seat as an immobilizer. Simply pack the space around the child with rolled towels or folded sheets taped as padding. Note that the car seat should be used only if it is not damaged.
(See Chapter 38, “Pediatrics,” for more information on immobilization of infants and toddlers.)

- **Elderly patients.** A possible limitation in an elderly patient is osteoporosis, a loss of mass that makes the bones extremely brittle and prone to fracture. In these cases, take extra care to avoid accidental injury. Make sure the patient understands what is happening and where you are taking her.

- **Patients with physical disabilities.** Use common sense in handling patients who have physical disabilities. The nature of the disability will let you know how to compensate. If, for example, the patient has fused joints or twisted limbs, position the patient to provide the greatest comfort. Take extra care in strapping. Whenever possible, use a rolled towel or other padding to support areas that might need it. Ask the patient to explain what positions are possible and comfortable for him.

## Packaging Patients for Air Transport

When the distance to the appropriate hospital is great or the patient’s condition is critical, the use of a helicopter or fixed-wing aircraft for patient transportation might be considered. (See Chapter 42, “Ambulance Operations and Air Medical Response,” for more detail on helicopter transport.) In this situation, there are some special considerations in packaging the patient to ensure safety of the patient, rescuers, and helicopter crew. Follow local protocols and air transportation companies for further guidelines.

1. Be sure that a patient who has been contaminated by a hazardous material has been thoroughly decontaminated. Especially in the confined space of a helicopter, it is possible for the crew to be overcome by hazardous fumes and lose control of the craft.

2. If at all possible and appropriate, have the patient’s airway managed with an endotracheal tube prior to the arrival of the aircraft.

3. Leave the chest accessible if the patient is intubated so the aircraft crew can assess the patient’s breath sounds prior to transport.

4. If the patient is to be transported by helicopter and is immobilized on a backboard, be sure the board is one that can be accommodated in the model of helicopter that will respond.

5. Be sure the patient is well secured to the backboard so as not to be jostled while moving to the aircraft or in flight.

6. Secure all equipment, blankets, sheets, and so on with tape so they cannot blow off the patient and into the rotor or engine of the aircraft. Secure all loose equipment at the scene.

7. Communicate to the patient what you are doing and prepare him to expect the noise and rotor wash of an incoming helicopter.

8. Cover the patient’s eyes, ears, and exposed wounds to protect them from the noise and rotor wash.

9. Consider having an engine company wet the landing zone to prevent dust and debris from being blown onto the rescuers, crew, and patient.

10. Have rescuers remove loose clothing or hats to avoid their being blown into the rotor or engine.

11. Do not approach the aircraft with the patient until instructed by the pilot or crew. Unless otherwise instructed, let the crew assist you in loading the aircraft. Stay well clear of the tail rotor, and observe all safety and danger placards. For everyone’s safety, learn how to approach an aircraft BEFORE an emergency call.

12. When moving the patient to be loaded into a helicopter, lay an IV bag on the patient’s chest instead of having it held up by a rescuer.

13. When loading a patient into a helicopter, minimize the number of people under the rotors at all times. Refer to local protocols and air transportation companies for further guidelines.

## GENERAL GUIDELINES FOR CARRYING A PATIENT USING A BACKBOARD, PORTABLE STRETCHER, OR FLEXIBLE STRETCHER

As mentioned previously, a wheeled device should be your preference to move a patient whenever possible. However, there are many situations in which the wheeled device is not feasible, such as moving a patient down or up steps, in a narrow hallway with angles, or over rough terrain. In those cases, you will use a backboard, portable stretcher, or flexible stretcher to move the patient either to the wheeled stretcher or directly to the back of the ambulance, depending on the situation. The method in which you position yourself to carry the patient is dependent on the number of EMTs or other emergency response personnel at the scene to assist with the lift and carry.

Some general guidelines for moving a patient on these devices are:

- Secure the patient to the device using a minimum of three straps.

- Secure the patient’s hands in the device so they cannot reach out and grab you or your partner, a railing, or other objects that may throw you and your partner off balance.

- Always carry the device with the patient’s feet first when going down steps or downhill.
• Always carry the device with the patient’s head first when going up steps or uphill.
• Consider your and your partner’s limitations as to weight and your ability to move the patient safely without further injury to the patient or yourselves.
• Know your limitations when considering moving patients from a unique situation such as a hillside, an unstable area, or a high angle, and seek assistance from properly trained rescuers.
• Constantly communicate with your partner or team to coordinate the move.
• Keep the patient’s weight as close to your body as possible.

Two-Person Carry

If only you and your partner are available for a carry, one EMT is positioned at the head of the patient while the other is at the foot. The stronger person should be at the head since most of the weight is at that end. The EMT at the foot end faces the EMT at the head end. This requires the EMT at the foot end to walk backward.

Be extremely cautious when employing this type of carry. One problem is that the EMT at the foot end can lose his balance by tripping over an unseen object. If a third person is available, place him behind the person at the foot end to act as a spotter. This person will often grasp the belt of the EMT at the foot end to provide balance and stabilization to that EMT. He will also call out obstacles to the EMT at the foot end. Another problem in this situation is that there is no EMT or rescuer to provide stabilization at the sides of the patient, so the carrying device can easily become unbalanced from side to side. Additionally, because only two EMTs are carrying the entire weight of the patient, they can fatigue quickly, which places them and the patient at greater risk for injury.

Four-Person Carry

When four emergency personnel are available, a different carrying configuration is often used. One rescuer is placed at the patient’s head. Another is placed at the foot end, facing forward with his hands behind his body to grasp the carrying device. The other two rescuers are placed at each side, facing forward and grasping the carrying device with the hand closest to the patient. This puts all rescuers facing forward, forming a diamond configuration.

An alternative rectangular configuration may be used when four rescuers are present. Two rescuers are placed on opposite sides of the carrying device on the head end and two rescuers on opposite sides at the foot end of the carrying device. All rescuers face forward and grasp the carrying device with the hand that is closest to the patient.

Carrying a Supine Patient on Stairs

A stair chair should be the device of choice to move a patient up or down stairs if the patient’s mental status and condition allow it. If the patient must be placed in a supine position to be moved up or down stairs, be sure the patient is secured to the device so he cannot slide out from either the foot or head end of the device. Also, be sure to secure the patient’s hands within the device so he cannot grab you, a railing, or any other object that could throw you off balance while carrying him.

When a supine patient is to be carried down stairs, typically one EMT is placed at the head end of the device facing the patient and the other is placed at the foot end of the device facing the patient with his back to the stairs. If possible, a spotter is placed behind the EMT at the foot end to provide guidance and stabilization and to count off the steps. The EMT at the foot end is first down the steps. This configuration is often used because of the limited width of a stairwell that doesn’t allow EMTs to be on both sides of the patient.

When moving a patient up steps, the same EMT configuration is used. The patient is carried head first; therefore, the EMT at the head end moves backward up the steps. If available, the spotter will be ahead of and guiding the EMT at the head end.

Neonatal Isolette

You may be required to transport a neonate from one medical facility to another in a neonatal isolette (Figure 6-24). The isolette is designed to keep the neonate in a warm environment to prevent hypothermia. Isolettes are wheeled devices that engage the typical stretcher mounts in the ambulance. It is important to ensure that the isolette can be properly secured in the ambulance. The isolette is either lifted into the ambulance or rolled in up a ramp.

![Figure 6-24](image-url) Neonatal isolette. (© Austin/Travis County START Flight)
EMT SKILLS 6-1

Power Lift

6-1A Get in position. Your feet should be about shoulder width apart, turned slightly outward, and flat on the ground.

6-1B As lifting begins, your back should remain locked and your feet should remain flat. Tighten the muscles of your back and abdomen to splint the lower back.

6-1C As you return to a standing position, make sure your back is locked in and your upper body comes up before your hips.
Position your arms under the patient. Be sure to cradle the head. If a third rescuer is available, he should slide both arms under the waist while the first two rescuers move their arms up and down as appropriate.

Lift the patient to your knees and roll toward your chests.

On signal, move the patient to the carrying device.
**EMT SKILLS 6-3**

**Extremity Lift**

- **6-3A** One rescuer should put one hand under each arm and grasp the wrists. The other should slip hands under the knees.
- **6-3B** Both rescuers should move up to a crouching and then standing position.

**EMT SKILLS 6-4**

**Direct Carry**

- **6-4A** Position your arms under the patient and slide the patient to the edge of the bed.
- **6-4B** Lift the patient and curl toward your chests.
- **6-4C** Rotate and place the patient gently on the carrying device.
**EMT SKILLS 6-5**

### Draw Sheet Method

- **6-5A** Reach across the stretcher and grasp the sheet firmly.
- **6-5B** Slide the patient gently onto the carrying device.

---

**EMT SKILLS 6-6**

### Loading the Roll-In Wheeled Stretcher

- **6-6A** Roll the stretcher to the ambulance.
- **6-6B** Roll the front of the stretcher into the ambulance until the safety mechanism engages.
- **6-6C** Disengage the carriage lock at the foot and roll the stretcher into the ambulance.
- **6-6D** Lock the stretcher into position.
Bariatric Stretchers

6-7A The Ferno LBS (large body surface) board converts a Ferno cot into a bariatric cot handling up to 1,000 pounds. (© Ferno-Washington, Inc.)

6-7B The Stryker MX-PRO® Bariatric Transport cot will handle patients from 850 to 1,600 pounds and can be used with accessory winch and ramp loading devices. (© Stryker Corporation)

Moving a Patient on a Stair Chair

6-8A Moving a patient up stairs in a stair chair—spotter above.

6-8B Moving a patient down stairs in a stair chair—spotter below.
Applying the Scoop Stretcher

- **6-9A** Adjust length of the scoop stretcher.
- **6-9B** Separate the stretcher halves.
- **6-9C** Gently slide half of the stretcher under the patient.
- **6-9D** Swing the remaining half of the stretcher into a closed position.
- **6-9E** Close and lock the stretcher halves.
- **6-9F** Lift the stretcher from its ends.
**SUMMARY**

Lifting and moving patients is a fundamental task performed by EMTs. Patients are often found on the second floor of a home, in a basement, around the corner in the bedroom, or down a narrow hallway—all of which require special techniques to move the patient safely to the wheeled stretcher and into the ambulance. To reduce your incidence of injury, always practice proper body mechanics and lifting techniques.

When moving a patient, be sure you know and understand how to perform the moves and what equipment is the safest for you and the patient. Always communicate with your team members and with the patient. Your priority is to avoid injury to you, your partner, other members of the emergency response team, and the patient. Select the best possible equipment to allow the patient to be moved in the safest manner, taking into consideration his condition. As an example, a patient with severe shortness of breath will not want to be moved lying supine. Thus, it may be necessary to use a stair chair to move him to the first floor.

Once the patient has been successfully moved, reassess the security of the straps and the device. Never leave the patient alone on the wheeled stretcher, especially if it is in a raised position.

---

**Case Study Follow-up**

**Scene Size-up**

You have been dispatched to a 72-year-old female patient, Amanda Sanchez, to take her on a routine transfer to the hospital dialysis center. As your partners unload the stair chair and blankets from the ambulance, you shovel the short walk to the front of the house and apply salt. While you are upstairs, the ice will have a chance to melt.

The patient's daughter opens the door and sends you up a flight of narrow stairs to the bedroom. Mrs. Sanchez greets you there, and you notice that she is using a walker. Your partners take in the stair chair and prepare it for the patient.

**Patient Assessment**

The training officer suggests that you practice taking a history and vital signs.

**Lifting and Moving the Patient**

After taking a history and vital signs, you listen as your training officer explains the procedure to the patient. She explains that you and your partner will place Mrs. Sanchez on the hospital blanket in the stair chair, tuck her in so she'll be warm, and secure her for a safe trip down the stairs.

Mrs. Sanchez asks if she will need her winter overcoat. Your partner explains that a warm hat and scarf would be okay, but the overcoat may be too bulky for the move. He promises her the blankets and the ambulance will keep her warm. He also says she can take the coat with her in case she needs it later. You and your partners then package the patient and move her to the stairwell.

At the top of the stairs, your training officer explains exactly what will be done next, while you and your partner quickly check the straps. When she's finished, the training officer says, "Mrs. Sanchez, remember? You may feel as if you're falling for a second. But you won't fall. We'll be holding you. Is it okay that we begin now?"

Mrs. Sanchez agrees, and you get behind the chair at the head. Your partner, who is taller than you, stands at the foot facing the patient. The training officer moves to the top of the steps to "spot." As you tilt the chair back, your partner grasps it by its legs. You then open the space between your feet, tighten your muscles to lock your back, make sure your hands and fingers are properly positioned, and bend from the hips to pick up the patient. You make sure you can keep the weight and arms as close to your body as possible. When you're both ready, you both say so.

Your training officer tells you how many steps there are ahead. Both of you start the descent. The trainer-spotter counts out the steps as you descend. You and the other carrier are keeping pace and checking in. The three of you sound like this:

- Two step. Okay. Too fast, slow down.
- Three step. Okay. Okay. (and so on)

You and your partner place the stair chair down at the bottom of the steps to rest for a minute. Mrs. Sanchez's daughter opens the front door, and the training officer checks to see that the walkway is clear of obstacles and ice. When you are all assured it is safe, you wheel the chair out to the ambulance and load the patient onto the ambulance cot.

**Reassessment**

Inside the ambulance, you make certain the patient is comfortable, loosening her scarf and the blankets. You perform a reassessment en route and arrive at the hospital without any change in the patient’s condition. You and your partners transfer Mrs. Sanchez to the hospital staff, complete the necessary paperwork, and then proceed to ready the ambulance for the next call.
IN REVIEW

1. List the four basic principles of body mechanics.
2. Explain how to perform the power grip, and when you should use it.
3. Explain how to perform the power lift, and when you should use it.
4. Name the three categories of patient moves, and explain when each should be used.
5. List some of the guidelines and safety precautions for carrying.

6. Explain, briefly, how to perform (a) a direct ground lift, (b) an extremity lift, (c) a direct carry, and (d) the draw sheet method.
7. Name the device that is recommended for carrying a patient up and down stairs, whenever possible, and explain the function of the spotter.
8. Name types of patient-carrying devices you would consider using if the spaces you need to traverse are too narrow or too confined for a wheeled stretcher.
9. Explain the proper body mechanics for reaching while doing a log roll.
10. Explain the safety guidelines for pushing and pulling.

CRITICAL THINKING

You are on the scene providing emergency care to a 76-year-old female patient who was found in bed on the second floor of her home. She is propped up in bed, using several pillows, and complains that she cannot breathe when lying flat. The bedroom is located down a narrow hallway.

1. What device should you use to move the patient to the ambulance?

2. What special circumstances should you consider when selecting the equipment?

3. How would you move the patient from the bed to the device being used to move her?

4. What body techniques will you use to prevent injury to yourself when performing the moves?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARDS** • Anatomy and Physiology; Medical Terminology

**COMPETENCIES** • Applies fundamental knowledge of the anatomy and function of all human systems to the practice of EMS.

Uses foundational anatomical and medical terms and abbreviations in written and oral communication with colleagues and other health professionals.

**OBJECTIVES** • After reading this chapter, you should be able to:

7-1. Define key terms introduced in this chapter.
7-2. Explain the importance of knowledge of anatomy and physiology to patient assessment and care.
7-3. Define the terms anatomy and physiology.
7-4. Describe each of the following terms of position:
   a. Anatomical position
   b. Supine
   c. Prone
   d. Lateral recumbent
   e. Fowler’s position
   f. Semi-Fowler’s position
   g. Trendelenburg position
   h. Shock position
7-5. Identify each of the following anatomical terms:
   a. Midline
   b. Sagittal plane
   c. Frontal plane
   d. Transverse plane
   e. Midaxillary line
   f. Midclavicular line
   g. Anterior and posterior
   h. Dorsal and ventral
   i. Right and left
   j. Superior and inferior
   k. Medial and lateral
   l. Proximal and distal
   m. Plantar
   n. Palmar
   o. Abdominal quadrants: right upper quadrant, left upper quadrant, left lower quadrant, right lower quadrant
7-6. State the function of each of the following musculo-skeletal system structures:
   a. Skeletal muscle
   b. Tendons
   c. Ligaments
   d. Bone
7-7. Describe each of the following components of the skeleton, including its location, the bones that make it up, and its function:
   a. Skull
      i. Cranium
   b. Spinal column
      i. Cervical spine
      ii. Thoracic spine
      iii. Lumbar spine
      iv. Sacral spine
   c. Thorax
      i. Sternum (including manubrium, body, and xiphoid process)
      ii. Ribs
   d. Pelvis
      i. Ilium and iliac crest
      ii. Ischium
   e. Upper extremities
      i. Clavicle
      ii. Scapula, including acromion process
      iii. Humerus
      iv. Radius
      v. Ulna, including olecranon process
      vi. Carpals
      vii. Metacarpals
      viii. Phalanges
7-8. Demonstrate each of the following joint movements:
   a. Flexion and extension
   b. Adduction and abduction
   c. Circumduction
   d. Pronation and supination

7-9. Describe each of the following types of joints:
   a. Ball-and-socket
   b. Hinge
   c. Pivot
   d. Gliding
   e. Saddle
   f. Condyloid

7-10. Differentiate between skeletal (voluntary), smooth (involuntary), and cardiac muscle.

7-11. Identify the basic functions of the respiratory system.

7-12. Identify the following structures of the respiratory system:
   a. Upper airway: nose, mouth, pharynx, nasopharynx, larynx
   b. Lower airway: trachea, bronchi, bronchioles, alveoli
   c. Epiglottis
   d. Lungs
   e. Pleura
   f. Diaphragm

7-13. Identify important differences in respiratory system anatomy in children.

7-14. Describe the basic mechanics and physiology of normal ventilation, respiration, and oxygenation, including:
   a. Inhalation and exhalation
   b. Use of intercostal muscles and diaphragm
   c. Negative and positive pressure
   d. Nervous system control of respiration
   e. Alveolar/capillary exchange of oxygen and carbon dioxide
   f. Capillary/cell exchange of oxygen and carbon dioxide

7-15. Identify characteristics of both adequate and inadequate breathing.

7-16. List the functions of the circulatory (cardiovascular) system.

7-17. Describe the anatomy and physiology of the heart to include:
   a. Location and size
   b. Tissue layers
   c. Chambers
   d. Valves
   e. Blood supply
   f. Blood flow through the heart
   g. Conduction system

7-18. Discuss the anatomy and physiology of the blood, circulation, perfusion, and metabolism to convey basic comprehension of:
   a. Arteries and arterioles
   b. Capillaries
   c. Veins and venules
   d. Blood composition
   e. Perfusion and capillary exchange
   f. Cell metabolism

7-19. Describe the basic functions of the nervous system.

7-20. Differentiate between the structural components and basic functions of the central nervous system and peripheral nervous system.

7-21. Differentiate between the functional divisions of the peripheral nervous system:
   a. Voluntary (somatic) nervous system
   b. Involuntary (autonomic) nervous system
      i. Sympathetic division
      ii. Parasympathetic division

7-22. Describe the basic role of the reticular activating system (RAS) and cerebral hemispheres in consciousness and unconsciousness.

7-23. Explain the overall function of the endocrine system.

7-24. Discuss the location and general function of each of the following components of the endocrine system:
   a. Thyroid gland
   b. Parathyroid glands
   c. Adrenal glands
   d. Gonads
   e. Islets of Langerhans of the pancreas, insulin, and glucagon
   f. Pituitary gland

7-25. Describe the general actions of epinephrine and norepinephrine on beta1, beta2, alpha1, and alpha2 receptors of the sympathetic nervous system.

7-26. List the general functions of the integumentary system.

7-27. Identify the structures of the integumentary system, including the epidermis, dermis, and subcutaneous layer.

7-28. Describe the basic anatomy and physiology of each of the following structures of the digestive system:
   a. Stomach
   b. Pancreas
   c. Liver
   d. Gallbladder
   e. Small intestine (duodenum, jejunum, ileum)
   f. Colon

7-29. List the basic structure and function of the organs of the urinary or renal system to include:
   a. Kidneys
   b. Ureters
   c. Urinary bladder
   d. Urethra

7-30. State the basic structure and function of the organs of the male and female reproductive systems:
   a. Male
      i. Testes
      ii. Accessory glands
      iii. Penis
   b. Female
      i. Ovaries
      ii. Fallopian tubes
      iii. Uterus
      iv. Vagina
      v. External genitalia

7-31. Explain the importance of knowledge of medical terminology in communication among health care team members.

7-32. Apply knowledge of common prefixes, suffixes, and roots to interpret medical terms.
INTRODUCTION

Knowledge of the human body and its systems is essential to high-quality patient assessment and emergency care. That understanding will help you recognize when the body is working as it should and when there are life-threatening deviations to normal function. Your ability to use proper terminology to describe the human body will also allow you to communicate patient information to other health care professionals concisely and accurately.

ANATOMICAL TERMS

Basic knowledge of the human body includes the study of anatomy and physiology. The word **anatomy** refers to the structure of the body and the relationship of its parts to each other (how the body is made). The word **physiology** refers to the function of the living body and its parts (how the body works).

As you proceed through your course, you will encounter descriptive terms you may not have heard or used before. Study and learn them. It is essential that you use them correctly to describe position, direction, and location of a patient and his illness or injury. Using correct terms minimizes confusion and helps to communicate the exact extent of a patient’s problem based on a careful physical assessment.

One term that is essential for you to understand and use is the **anatomical position**. Unless otherwise indicated, all references to the human body assume the anatomical position: The patient is standing erect, facing forward, with arms down at the sides and palms forward. This basic position is used as the point of reference whenever terms of direction and location are used. Other terms of position include (Figures 7-1a to 7-1f ■):

- **Supine**. The patient is lying face up on his back.
- **Prone**. The patient is lying face down on his stomach.
- **Lateral recumbent (recovery) position**. The patient is lying on his left or right side. Be sure to place the patient on the side so that you can easily monitor the airway. Also, be careful not to allow excessive pressure on the chest that might impair the breathing status of the patient. To avoid possible injury from impaired blood flow to the lower arm, turn the patient to the opposite side if he is in the recovery position for greater than 30 minutes.
- **Fowler’s position**. The patient is lying on his back with his upper body elevated at a 45° to 60° angle.
- **Semi-Fowler’s position**. The patient is lying on his back with the upper body elevated at an angle less than 45°.
- **Trendelenburg position**. The patient is lying on his back with the legs elevated higher than the head and body on an inclined plane (head down, legs up). This position, which was once used in the management of shock, is no longer recommended. With the patient in the Trendelenburg position, the abdominal organs may be pushed up against the diaphragm, from gravity, and make breathing more difficult for the patient.

Case Study

**The Dispatch**

EMS Unit 108—respond to Centennial Park on Highland Avenue—you have a female patient at that location who suffered a burn—time out 1306 hours.

**Upon Arrival**

After positioning the ambulance out of the flow of traffic, you scan the scene for hazards and exit. A woman runs up to you and says, “A woman over here was trying to refuel her son’s model airplane when the gas tank blew up or something.” You approach the patient and find that she is sitting on a patch of grass about 15 feet away from a smoldering model plane.

How would you proceed to assess and care for this patient?

*During this chapter, you will read a brief overview of the human body. Later, we will return to the case study and put in context some of the information you learned.*
It may also increase the pressure inside the skull in patients with a head injury. It is definitely contraindicated in a patient with a suspected spine injury.

- **Shock position.** This is an alternative to the Trendelenburg position, where only the feet and legs are elevated approximately 12 inches. *Like the Trendelenburg position, the shock position is no longer recommended in the treatment of shock. This position is also contraindicated in a patient with a suspected spine injury.* You may find this position still used for the patient who has suffered a simple faint.

In assessing a patient’s condition, it is important to know certain external and internal landmarks, or the anatomical regions of the body and related parts (Figures 7-2 through 7-9). Referring to these landmarks makes your description of the patient’s condition more understandable, especially when you are seeking on-line medical direction.

Imaginary divisions of the body are called **anatomical planes.** There are also anatomical lines used to reference points on the body. These planes and lines indicate the internal body structure and the relationship of different groups of organs to others. Anatomical planes and lines are delineated by the following (Figures 7-2 and 7-3):

- **Sagittal plane.** The sagittal plane, or median plane, is a vertical plane that runs lengthwise and divides the

---

**FIGURE 7-1a** Supine position.

**FIGURE 7-1b** Prone position.

**FIGURE 7-1c** Right lateral recumbent position.

**FIGURE 7-1d** Left lateral recumbent position.

**FIGURE 7-1e** Fowler’s position.

**FIGURE 7-1f** Trendelenburg position.

---
body into right and left segments. The segments do not have to be equal. If the plane divides the body into two equal halves it would be referred to as the midsagittal plane.

- **Frontal or coronal plane.** The frontal or coronal plane divides the body into front and back halves.

- **Transverse or horizontal plane.** The transverse or horizontal plane is parallel with the ground and divides the body into upper and lower halves. It may also be referred to as the axial plane.

- **Midline.** Visualize the normal anatomical position (the patient is facing you). Now imagine a line drawn vertically through the middle of the patient’s body, beginning at the top of the head and continuing down through the nose and the navel and to the ground between the legs. Midline corresponds with the midsagittal plane because it divides the body into equal halves.

- **Midaxillary line.** Visualize a patient standing in profile. Now draw an imaginary line vertically from the middle of the patient’s armpit down to the ankle. This is the midaxillary line. A vertical line drawn side to side through the body from the midaxillary line on one side to the midaxillary line on the opposite side forms the frontal plane and divides the body into the anterior plane (the patient’s front) and the posterior plane (the patient’s back).

- **Transverse line.** Visualize the normal anatomical position. Draw an imaginary line horizontally through the patient’s waist. This is the transverse line. A horizontal line drawn through the body, front to back, at the waist forms the transverse plane and divides the body into the superior plane (above the waist) and the inferior plane (below the waist).

Other descriptive terms include (Figure 7-3):

- **Anterior and posterior.** *Anterior* is toward the front. *Posterior* is toward the back.

- **Superior and inferior.** *Superior* means toward the head or above the point of reference. *Inferior* means toward the feet or below the point of reference.

- **Dorsal and ventral.** *Dorsal* means toward the back or backbone (spine). *Ventral* means toward the front or belly (abdomen).

- **Medial and lateral.** *Medial* means toward the midline or center of the body. *Lateral* refers to the left or right of the midline, or away from the midline of the body. Note that *bilateral* refers to both left and right, meaning “on both sides.” *Unilateral* refers to one side. *Ipsilateral* refers to the same side, *contralateral* to the opposite side.

- **Proximal and distal.** *Proximal* means near the point of reference. *Distal* is distant, or far from the point of reference.

- **Right and left.** Always the patient’s right and left.

- **Midclavicular and midaxillary.** *Midclavicular* refers to the center of each of the collarbones (clavicle). The midclavicular line (Figure 7-5) extends from the center of either collarbone down the anterior thorax. *Midaxillary* refers to the center of the armpit (axilla). The midaxillary line (Figure 7-7) extends from the middle of the armpit to the ankle.

- **Plantar and palmar.** *Plantar* refers to the sole of the foot. *Palmar* refers to the palm of the hand.

The abdomen may be referred to as if it were divided by horizontal and vertical lines drawn through the umbilicus (navel). The four parts, or abdominal quadrants (Figure 7-10), are the right upper quadrant (RUQ), right lower quadrant (RLQ), left upper quadrant (LUQ), and left lower quadrant (LLQ).

## BODY SYSTEMS

### The Musculoskeletal System

The musculoskeletal system of the human body consists of a bony framework, or skeleton, held together by ligaments that connect bone to bone, layers of muscles, tendons that connect muscles to bones, and various other connective tissues. The system must be strong to...
provide support and protection, jointed to permit motion, and flexible to withstand stress.

**The Skeletal System**

The skeletal system serves four functions:

- Giving the body its shape
- Protecting the vital internal organs
- Allowing for movement
- Storing minerals and producing blood cells

The skeletal system has six basic components: the skull, spinal column, thorax, pelvis, and the upper and lower extremities (Figure 7-11). The bones of the adult skeleton are classified by size and shape (long, short, flat, or irregular).

**The Skull.** The skull rests at the top of the spinal column and houses and protects the brain. It has two parts: the cranium and the face.

The cranium forms the top, back, and sides of the skull plus the forehead. The interlocking bones of the cranium—the *occipital*, *two parietal*, *two temporal*, and the *frontal*—are typical flat bones. The outer layer of the cranium is thick and tough. The inner layer is thinner and more brittle. Though this arrangement provides for maximum strength, lightness, and elasticity, the cranium may still be fractured. The brain is commonly lacerated...
FIGURE 7-4 Regions of the body.

FIGURE 7-5 Terms describing the anterior chest.
by the bony projections and ridges on the anterior and inferior surfaces of the skull. Impact also can bruise the brain and cause it to bleed and swell. Because the cranium cannot expand, bleeding and swelling increase pressure within the brain and can lead to unresponsiveness or death.

**PATHOPHYSIOLOGY PEARLS**

Bleeding and swelling within the cranium may compress brain tissue, causing it to malfunction and possibly die.

The area between the brow and chin—the **face**—has 14 bones, 13 of which are immovable and interlocking. The immovable bones form the bony settings of the eyes, nose, cheeks, and mouth. Among them are the **orbits** (the eye sockets), the **nasal bones** (the bed of the nose), the **maxillae** (fused bones of the upper jaw), and the **zygomatic bones** (cheekbones). The **mandible** (lower jaw) moves freely on hinge joints. Shaped like a horseshoe, it is the largest and strongest bone of the face.

**The Spinal Column.** The **spinal column**, or **vertebral column**, is the principal support system of the body. Ribs originate from it to form the thoracic (chest) cavity. The rest of the human skeleton is directly or indirectly attached to the spine as well.

The spinal column is made up of irregularly shaped blocks of bone called **vertebrae** and has a great deal of mobility. Lying one on top of the other to form a column, the vertebrae are bound firmly together by strong ligaments. If any vertebrae are crushed or displaced, the spinal cord (which is housed inside the spinal column) may be squeezed, stretched, torn, or severed.

**ASSESSMENT TIPS**

Damage to the spinal cord will typically produce a loss of sensation or movement distal to the injury, whereas an injury to the spinal column (vertebrae) will usually produce only pain.

Between each two vertebrae is a fluid-filled pad of tough elastic cartilage called the **intervertebral disk**. The intervertebral disks act as shock absorbers and allow for movement of the spine. The disks are extremely susceptible to injury from twisting, grinding, or improper lifting of heavy objects.
The spinal column is composed of 33 vertebrae divided into the following five parts: cervical, thoracic, lumbar, sacral, and the coccyx.

- **Cervical spine**, C1–C7 (neck). The first seven vertebrae form the cervical spine, which is the most prone to injury.
- **Thoracic spine**, T1–T12 (upper back). The 12 thoracic vertebrae that are directly inferior to the cervical spine form the upper back. The 12 pairs of thoracic ribs are attached to the spine posteriorly and help support the vertebrae.
- **Lumbar spine**, L1–L5 (lower back). The next five vertebrae form the lower back, and are the least mobile of the vertebrae. Most lower-back injuries involve muscles, not vertebrae.
- **Sacral spine**, S1–S5 (back wall of the pelvis). The next five vertebrae are fused together to form the rigid part of the posterior side of the pelvis.
- **Coccyx** (tailbone). The last four vertebrae are fused together and do not have the protrusions characteristic of the other vertebrae.

**The Thorax.** The thorax, or chest, is composed of the ribs, the **sternum** (the breastbone), and the thoracic spine. The 24 ribs are semiflexible arches of bone, which are arranged in 12 pairs and are attached posteriorly by
ligaments to the 12 thoracic vertebrae. The first seven pairs of ribs are attached to the sternum by cartilage and are called the **true ribs**. The next three pairs are attached to the ribs above them by cartilage. The front ends of the last two pairs—the floating ribs—are not attached to the sternum. These last five pairs of ribs are referred to as **false ribs**.

The sternum is a flat, narrow bone in the middle of the anterior chest. The **clavicle** (collarbone) is attached to the superior portion of the sternum called the **manubrium**. The ribs are attached to the middle segment, or body, of the sternum. The inferior portion of the sternum is the **xiphoid process**.

**The Pelvis.** The **pelvis** is a doughnut-shaped structure that consists of several bones, including the sacrum and the coccyx. At each side of the pelvis is an **iliac crest**. The iliac crests form the “wings” of the pelvis. The **pubis** is in the anterior and inferior portion of the pelvis, and the **ischium** is in the posterior and inferior portion. The pelvis forms the floor of the abdominal cavity. The pelvic cavity supports the intestines and houses the bladder, rectum, and internal reproductive organs.

**The Lower Extremities.** The limbs of the body, the arms and legs, are known as the **extremities**. The legs from the hip to the toes are called the **lower extremities**. On the lateral aspect of each hip is the **acetabulum**, into which fits the rounded top, or head, of the **femur** (thighbone).

The bottom of the femur is flat with two projections that help to form the hinged knee joint, which like the elbow allows angular movement only. The knee joint is protected and stabilized in front by the **patella** (kneecap), a small, triangular-shaped bone. Because the patella usually receives the force of falls or blows to the knee, it is often bruised and can be fractured.

The two bones of the lower leg are the **tibia** (shin) and the **fibula**. The tibia is the weight-bearing bone located at the anterior and medial side of the leg. Its broad upper surface receives the rounded end of the distal femur to form the knee joint. The much smaller distal end of the tibia forms the medial malleolus of the ankle. The fibula is attached to the tibia at the top and is located at the lateral side of the leg parallel to the tibia.

The bony prominences at the ends of the tibia and fibula form the ankle joint socket. The medial and lateral **malleolus** are the knobby surface landmarks of the ankle joint. A group of bones, including the **calcaneus** (heel bone), are called the **tarsals** and make up the proximal portion of the foot. Five **metatarsals** form the substance of the foot, and 14 **phalanges** on each foot form the toes (two in the big toe and three in each other toe).

**The Upper Extremities.** The upper limbs, including the shoulders, arms, forearms, wrists, and hands, are called the **upper extremities**. Each clavicle (collarbone) and **scapula** (shoulder blade) form a shoulder girdle, the tip of which is called the **acromion**. The powerful muscles of the shoulder girdle help attach the arms to the trunk and extend from it to the arms, thorax, neck, and head.

The proximal portion of the arm is the **humerus**, the largest bone in the upper extremity. Its shaft is
The skeletal system.
roughly cylindrical, its upper end is round, and its lower end is flat. The round head of the humerus fits into a shallow cup in the shoulder blade, forming a ball-and-socket joint that is the most freely movable and easily dislocated joint in the body.

The hinged elbow joint is made up of the distal end of the humerus plus the proximal ends of the radius (the lateral bone of the forearm) and the ulna (the medial bone of the forearm). The radius is located on the thumb side and the ulna is found on the little-finger side of the forearm. The olecranon is a part of the ulna that forms the bony prominence of the elbow. While the ulna can be felt through the skin with your fingertips, the upper two-thirds of the radius cannot because it is sheathed in muscle tissue. Only the lower third of the radius, which enlarges to form most of the wrist joint, can be felt through the skin.

The wrist consists of eight bones called the carpals. The structural strength of the hand comes from the metacarpals. The bones that make up the fingers and thumbs are the phalanges (three per finger, two per thumb).

The Joints. The place where one bone connects to another is called a joint. Some joints are immovable (as in the skull), others are slightly movable (as in the spine), and the remaining joints such as the elbow and knee are movable (Figure 7-12). Movable joints allow changes of position and motion as follows:

- **Flexion.** Bending toward the body or decreasing the angle between the bones or parts of the body
- **Extension.** Straightening away from the body or increasing the angle between the bones or parts of the body
- **Abduction.** Movement away from the midline
- **Adduction.** Movement toward the midline
- **Circumduction.** A combination of the four preceding motions as is possible with the shoulder joint
- **Pronation.** Turning the forearm so the palm of the hand is turned toward the back
- **Supination.** Turning the forearm so the palm of the hand is turned toward the front

The structure of the joint determines the kind of movement that is possible. Types of joints include the following, the most common of which are the ball-and-socket joint and hinged joint (Figure 7-13):

- **Ball-and-socket joint.** This type of joint permits the widest range of motion—flexion, extension, abduction, adduction, and rotation. Examples: joints at the shoulder and hip.
- **Hinged joint.** Hinged joints (such as those in the elbow, knee, and finger) permit flexion and extension. Elbow joints have forward movement (the anterior bone surfaces approach each other), while knee joints have backward movement (the posterior bone surfaces approach each other).
- **Pivot joint.** This type of joint allows for a turning motion, and includes the joints between the head and neck at the first and second cervical vertebrae and those in the wrist.
- **Gliding joint.** The simplest movement between bones occurs in a gliding joint, where one bone slides across another to the point where surrounding structures restrict the motion. Gliding joints connect the small bones in the hands and the feet.
- **Saddle joint.** This joint is shaped to permit combinations of limited movements along perpendicular planes. For example, the ankle allows the foot to turn inward slightly as it moves up and down.
- **Condyloid joint.** This is a modified ball-and-socket joint that permits limited motion in two directions. In the wrist, for example, it allows the hand to move up and down and side to side, but not to rotate completely.

**Bone Injury**

A fracture is a loss of continuity in the structure of a bone. When a fracture to a bone occurs, the sharp fragments may injure surrounding tissue, such as nerves, vessels, and connective tissue. However, it is important to note that bones are also living tissue and have a rich blood supply. If a bone is fractured, the vessels within the bone may be torn or ruptured (Figure v-14). This sometimes leads to severe bleeding from the bone itself rather than from the surrounding vessels or tissue. A patient can lose from 1,000 to 2,000 mL of blood from
a fractured femur. A bleeding pelvic fracture may cause the loss of up to 2,000 mL of blood into the pelvic cavity. Thus, when assessing a patient who has suffered a bone fracture, look for signs and symptoms of bleeding at the fracture site. Also, if the bleeding is severe, be aware that it may produce a shock state.

The Muscular System

Movement of the body is due to work performed by the muscles (Figure 7-15 ■). What enables muscle tissue to work is its ability to contract (to become shorter and thicker) when stimulated by a nerve impulse. The cells of a muscle are called fibers, because they are usually long and threadlike. Each muscle has countless bundles of closely packed, overlapping fibers bound together by connective tissue.

Muscles can be injured in many ways. Overexerting a muscle may tear fibers, and muscles subjected to trauma can be bruised, crushed, cut, torn, or otherwise injured, even if the skin is not broken. Muscles injured in any way tend to become swollen, tender, painful, or weak.

There are three kinds of muscle: skeletal (voluntary), smooth (involuntary), and cardiac muscle (Figure 7-16 ■).

Skeletal Muscle. Under the control of the brain and nervous system, skeletal muscle, or voluntary

- Tibialis anterior

**Figure 7-15** The muscular system.
Smooth Muscle. Smooth muscle, or involuntary muscle, is made up of large fibers that carry out the automatic muscular functions of the body through rhythmic, wavelike movements. For example, smooth muscles move blood through the veins, bile from the gallbladder, and food through the digestive tract. The individual has no direct control over this type of muscle, though it responds to stimuli such as stretching, heat, and cold.

Smooth muscle is found in the walls of tubelike organs, ducts, the respiratory tract, and blood vessels and forms much of the walls of the intestines and urinary system. Vasoconstriction, decreasing the diameter of the vessel, and vasodilation, increasing the diameter of the vessel, are controlled by smooth muscle within the vessels (Figure 7-17). Vasoconstriction increases the resistance inside the vessel, making it harder for the blood to pass through, and results in an increase in pressure. Conversely, vasodilation results in a decrease in the resistance inside the vessel, making it easier for the blood to flow through, and decreasing the pressure.

Cardiac Muscle. Found only in the walls of the heart, cardiac muscle is a special kind of involuntary muscle particularly suited for the work of the heart. It has the property of automaticity. That is, it has the ability to generate an impulse on its own, even when disconnected from the central nervous system.

Although it is smooth like smooth muscle but striated (stringlike) like skeletal muscle, cardiac muscle is made up of a cellular meshwork that is unlike either smooth or skeletal muscle. It has its own blood supply, furnished by the coronary artery system, and cannot tolerate interruption of the blood supply for even very short periods.

The Respiratory System

Basic Functions and Structures

The body can store food for weeks and water for days, but it can store enough oxygen to last only a few
minutes. Simple inhalation normally provides the body with the oxygen it needs. However, if the oxygen supply is cut off, as in a drowning or choking patient, brain cells will ordinarily begin to die in about 5 minutes.

The basic functions of the respiratory system are:

- Respiration
- Ventilation
- Oxygenation and removal of carbon dioxide
- Serving as a buffer to maintain a normal acid-base balance

**Respiration** refers to the process of moving oxygen and carbon dioxide across membranes, in and out of the alveoli, capillaries, and cells. Thus, respiration deals with the actual gas exchange process. **Oxygenation** is the form of respiration in which oxygen molecules move across a membrane from an area of high oxygen concentration to an area of low oxygen concentration. Cells are oxygenated when the oxygen moves out of the blood in the vessel and into the cell where it is used in metabolism. **Ventilation** is the mechanical process by which air is moved in and out of the lungs. Ventilation is primarily based on changes in pressure inside the chest that cause air to flow into or out of the lungs. The mechanics and control of ventilation will be covered in more detail in Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

The body also relies on the respiratory system to assist in regulating the balance of acid and base elements in the body. Respiration is one of three mechanisms by which the body regulates acid-base balance. (The other two are kidney function and the bicarbonate buffer system, which works through combinations of hydrogen, bicarbonate ions, and carbonic acid.) As the acid level in the body increases, the respiratory system increases the rate and depth of respirations to exhale excess carbon dioxide, which in turn works to decrease the body's acid load.

Oxygen from the air is transported to the blood through the **respiratory system** (Figure 7-18). The airway is separated into an upper and a lower airway. The upper airway consists of the following structures:

- Nose and mouth
- Pharynx
- Nasopharynx
- Larynx

The upper airway ends at the level of the cricoid cartilage, the ring that forms the most inferior portion of the larynx. The lower airway is composed of the following structures:

- Trachea
- Bronchi
- Bronchioles
- Alveoli

The major components of the respiratory system are described in the following paragraphs.

**The Nose and Mouth.** Air normally enters the body through the nose and mouth. There it is warmed, moistened, and filtered as it flows over the damp, sticky mucous membranes.

**The Pharynx.** From the back of the nose or mouth, the air enters the pharynx (throat), the common pas sageway for food and air. Air from the mouth enters through the oral portion of the pharynx, or the oropharynx. Air from the nose enters the nasal portion of the pharynx, or the nasopharynx. At its lower end the pharynx divides into two structures—the esophagus, which leads to the stomach, and the trachea, which leads to the lungs. The trachea is anterior to the esophagus.

**The Trachea and Larynx.** The trachea carries air from the nose and mouth to the lungs. Immediately superior to the trachea is the larynx, which houses the vocal cords and is commonly called the “voice box.” The “Adam’s apple” or thyroid cartilage is the anterior cartilage that covers the larynx. The larynx can be easily felt through the skin with your fingertips at the front of the neck. The most inferior part of the larynx is the cricoid cartilage, a firm, full ring of cartilage that forms the lower edge of the larynx.

**The Epiglottis.** The trachea is protected by a small, leaf-shaped flap called the epiglottis. Usually, this flap automatically covers the entrance of the larynx during swallowing to keep food and liquid from entering the trachea and lungs. When a patient swallows, the epiglottis moves downward and the larynx moves upward, creating a seal over the opening to the larynx. However, during an altered mental status or unresponsiveness, reflexes may not work properly. If liquid, blood, vomit, or another substance is in the mouth of an unresponsive patient, it may be aspirated into the trachea and lungs and cause impaired exchange of oxygen and carbon dioxide.

**The Bronchi.** The distal portion of the trachea branches into two main tubes, or bronchi, one branching off to each lung. Each bronchus divides and subdivides into smaller bronchioles, somewhat like the branches of a tree. The bronchioles are lined with smooth muscle and have the ability to constrict (bronchoconstriction) or dilate (bronchodilation) to certain stimuli. If bronchoconstriction occurs, the smooth muscle contracts, decreasing the diameter of the bronchiole, thereby increasing the resistance and making it more difficult to move air (Figure 7-19). During bronchodilation, the smooth muscle relaxes, making the diameter of the bronchiole larger. This lessens the resistance and makes it easier to move air through the bronchiole. Thus, bronchoconstriction would make it more difficult for a patient to breathe, and bronchodilation would make it easier because of the changes in the resistance. This principle could be related to lifting a
Respiratory System

- **nasal cavity**: Cleanses, warms, and humidifies inhaled air.
- **pharynx & larynx**: Carries air to the trachea and produces sound.
- **trachea**: Transports air to and from lungs.
- **bronchial tubes**: Air passageways inside the lung.
- **lungs**: Site of gas exchange between air and blood.

**FIGURE 7-18** The respiratory system.
weight. A heavier weight produces a greater resistance and a muscle has to work harder to lift it. However, a lighter weight has less resistance, thus, it is easier to lift. A greater resistance increases the work of breathing.

At the ends are thousands of tiny air sacs called alveoli, each enclosed in a network of capillaries (tiny blood vessels). This is the site of gas exchange in the lungs.

The Lungs. The principal organs of respiration are the lungs, two large, lobed organs that house thousands of tiny alveolar sacs responsible for the exchange of oxygen and carbon dioxide (as will be explained later). A thin layer of connective tissue called the visceral pleura covers the outer surface of the lungs. A layer of thicker, more elastic tissue called the parietal pleura covers the internal chest wall. Between the two layers is the pleural cavity, a tiny space with negative pressure that allows the lungs to stay inflated with air (Figure 7-20).

The Diaphragm. A powerful, dome-shaped muscle essential to breathing, the diaphragm also separates the thoracic cavity from the abdominal cavity.

Anatomy in Infants and Children

When treating infants or children, remember the anatomical differences in the respiratory system (Figure 7-21):

- The mouth and nose are smaller than those of adults and are more easily obstructed by even small objects,
blood, or swelling. Therefore, extra attention to keeping the airway open is required when treating an infant or child.

- The tongue of an infant or child takes up proportionally more space in the pharynx and it can block the pharynx more easily, again with implications for care of the infant or child's airway.
- Infants and children have narrower tracheas that may be obstructed more easily by swelling or foreign bodies. The trachea is also softer and more flexible than that of an adult. Therefore, hyperextension of the head (tipping the head back), or flexion (allowing the head to tip forward), can occlude the trachea. Because the head of an infant or young child is quite large relative to the body, it is necessary to place a folded towel or similar item about one inch thick under the shoulders to keep the trachea aligned and open (“sniffing” position).
- The cricoid cartilage is less developed and much less rigid. Therefore, the maneuver of pressing on the cricoid cartilage to help in placing a tube into the trachea, often used on adults, is not appropriate for an infant or child, since it can depress the soft cartilage and result in obstruction.
- Because the chest wall is softer, infants and children rely more heavily on the diaphragm for breathing. Excessive movement of the diaphragm is a sign of respiratory distress in an infant or child, evidenced by increased movement of the abdominal wall.

**Assessment Tips**
The immature respiratory chest muscles of the infant and young child often mean they need to use their abdominal muscles more during breathing; thus, you would expect to see more exaggerated abdominal movement during normal breathing. ■

**Pathophysiology Pearls**
The phrenic nerve, which exits the spinal column between the third and fifth cervical vertebrae, transmits the electrical impulses that cause the diaphragm to contract. ■

### Mechanics of Ventilation
During inhalation the diaphragm and the **intercostal muscles** (the muscles between the ribs) contract, increasing the size of the thoracic cavity. The diaphragm moves slightly downward, flaring the lower portion of the rib cage, which moves upward and outward. This creates a negative pressure in the chest, which causes air to flow into the lungs. During exhalation the diaphragm and intercostal muscles relax, decreasing the size of the thoracic cavity. The diaphragm moves upward; the ribs move downward and inward, creating a positive pressure within the thorax and causing air to flow out of the lungs (Figure 7-22 ■). The diaphragm contributes about 60–70 percent of the effort to breathe, whereas the intercostal muscles contribute the remaining 30–40 percent. Thus, a significant injury that prevents the diaphragm from functioning properly will cause the patient’s breathing to become ineffective.

The diaphragm receives its stimulation to contract from the phrenic nerve that exits the spinal cord at the cervical spine between vertebrae C3 and C5. If a spinal cord injury occurs at C3 to C5, the phrenic nerve may be damaged and the diaphragm will not receive a nervous impulse to contract, no longer allowing it to contribute to ventilation. The intercostal muscles will also not work properly because the nerves that stimulate these muscles exit from the lower thoracic vertebrae. With an injury to the spinal cord high in the cervical vertebrae, the patient would not be able to breathe spontaneously and would require artificial ventilation.
**Physiology of Respiration**

In the lungs, oxygen and carbon dioxide are exchanged through the thin walls of the alveoli and the capillaries (Figures 7-23 and 7-24). In alveolar/capillary exchange, oxygen-rich air enters the alveoli during each inspiration and passes through the capillary walls into the bloodstream. Carbon dioxide and other waste gases move from the blood through the capillary walls into the alveoli and are exhaled. In capillary/cellular exchange throughout the body, carbon dioxide moves from the cells to the capillaries, and oxygen moves from the capillaries to the cells.

**Adequate and Inadequate Breathing**

*Adequate breathing* is characterized by an adequate respiratory rate and tidal volume. Respiratory rate is the number of breaths a patient takes in one minute. Tidal volume (VT) is the amount of air the patient breathes in and out with one regular breath. There is a wide variety of normal ranges of respiratory rates. In adults, the normal range is 8 to 24 breaths per minute, with the average between 12 and 20 breaths per minute. Elderly patients have higher resting respiratory rates that average 20 to 22 per minute. A normal range for children is typically 15 to 30 breaths per minute. Infants typically breathe 25 to 50 breaths per minute. As the infant or child ages, his respiratory rate will decrease. The respirations should be regular in rhythm and free of unusual sounds, such as wheezing. The chest should expand outward and equally with each breath, indicating an adequate depth (tidal volume). The chest wall of an average-sized adult will move outward about 1 inch with each inhalation. Breathing should be virtually effortless (accomplished without the use of accessory muscles of the neck, chest, or abdomen).

*Inadequate breathing* may be characterized by:
- Rates that are either too slow or too fast as compared to what is normal for the patient
- Irregular pattern of breathing resulting from an illness or injury
- Diminished or absent breath sounds, indicating an inadequate volume of air being breathed in and out
- Unequal chest expansion, indicating a chest wall injury that could reduce the tidal volume

![FIG 7-23](image-url) Alveolar/capillary gas exchange.

![FIG 7-24](image-url) Capillary/cell gas exchange.
• Inadequate chest expansion, indicating a poor volume of air being breathed in (referred to as shallow breathing)
• Pale or bluish mucous membranes or skin that may also be cool and clammy, indicating poor oxygen exchange (respiration and oxygenation)
• Use of accessory muscles, identified by retractions above the clavicles, between the ribs, and below the rib cage and use of the muscles in the neck during breathing, especially among infants and children, indicating an increased work effort to breathe
• Nasal flaring, especially in children, indicating an increased work effort to breathe
• “Seesaw” breathing in infants (the chest and abdomen move in opposite directions)
• Head bobbing, where the head bobs upward on inhalation and downward toward the chest on exhalation, indicating severe respiratory fatigue
• Agonal respirations (occasional gasping breaths) that may be seen just before death
• Grunting, especially in newborns, heard at the end of inspiration or the beginning of exhalation

For the breathing to be considered adequate, both rate and tidal volume must be adequate. If either rate or tidal volume is inadequate, the breathing is considered inadequate, and immediate ventilation is necessary.

The Circulatory System

The circulatory system is composed of the heart, blood vessels, and blood (Figure 7-25a). It is a closed system that transports blood to all parts of the body. Blood brings oxygen, nutrients, and other essential chemical elements to tissue cells, and removes carbon dioxide and other waste products resulting from cell metabolism.

The circulatory system has several functions:

• Providing a medium for perfusion of cells with oxygen and other nutrients and removal from the cells of carbon dioxide and other waste products
• Transporting blood to cells and the alveoli for gas exchange
• Serving as a reservoir to house blood
• Serving as a medium for buffering the body’s acid-base balance
• Providing a mechanism to deliver immune cells and other substances to fight infection
• Containing substances that promote clotting

Basic Anatomy

The Heart. The heart, a highly efficient pump, is a chambered muscular organ that lies within the chest in the thoracic cavity between the two lungs. In size and shape, it resembles a closed fist. About two-thirds of its mass is located to the left of the midline of the body. Its lower point, the apex, lies just above the diaphragm.

The pericardium is a double-walled sac that encloses the heart, gives support, and prevents friction as the heart moves within this protective sac. The surfaces of the pericardial sac produce a small amount of fluid lubrication needed to facilitate the normal movements of the heart.

The heart has four chambers. (The flow of blood to and from the lungs and the body and through the four chambers is shown in Figure 7-25b.) The upper chambers, called the atria, receive blood from the veins. The right atrium receives oxygen-depleted blood from the veins of the body. The left atrium receives oxygen-rich blood from the pulmonary veins from the lungs.

The lower chambers are called ventricles. They pump blood out to the arteries. The right ventricle pumps oxygen-depleted blood to the pulmonary arteries, which transport the blood to the lungs where it will be oxygenated. The left ventricle pumps oxygen-rich blood to the major artery from the heart, the aorta (see the description that follows), from which the blood is gradually delivered to all body cells.

A series of valves between the chambers of the heart keep the blood flowing in one direction and prevent the backflow of blood. The four valves are:

• Tricuspid valve. Between the right atrium and the right ventricle
• Pulmonary valve. At the base of the pulmonary artery in the right ventricle
• Mitral valve, also known as the bicuspid valve. Between the left atrium and the left ventricle
• Aortic valve. At the base of the aortic artery in the left ventricle

The heart is composed of specialized contractile and conductive muscle that responds to electrical impulses. A sophisticated cardiac conduction system (Figure 7-25c) causes the myocardium, or middle layer of muscle, to contract and eject blood from the heart. The electrical impulse originates at the sinoatrial (SA) node and travels to the atrioventricular (AV) node, which is located between the atria and the ventricles, and finally through the bundle of His to the Purkinje fibers to the ventricles. As the heart muscle contracts, blood is propelled through the pulmonary arteries and to the lungs and into the aorta. From the aorta, it is eventually circulated throughout the body.

The Arteries. An artery carries blood away from the heart (Figure 7-26a). All arteries except the pulmonary arteries carry oxygen-rich blood. The major arteries include the following:

• Aorta. The major artery from the heart, the aorta, lies in front of the spine and passes through the thoracic and abdominal cavities. At about the level of the navel, the aorta divides into the iliac arteries, allowing blood to travel down each leg. The aorta and its branches supply all other arteries with blood.
• Coronary arteries. The coronary arteries are the vessels that supply the heart itself with blood (Figure 7-25d).
Cardiovascular System

- **heart**: Pumps blood through blood vessels
- **artery**: Carries blood away from the heart
- **vene**: Carries blood toward the heart
- **capillary**: Exchange site between blood and tissues

**FIGURE 7-25a** The circulatory system. (Red indicates arteries; blue indicates veins.)
**FIGURE 7-25b** Blood flow through the chambers of the heart.

**FIGURE 7-25c** The cardiac conduction system.
• **Carotid arteries.** The carotid arteries (one on each side of the neck) supply the brain and head with blood. Pulsations of the carotid arteries can be felt on either side of the neck.

• **Femoral arteries.** The femoral artery is the major artery of the thigh and supplies the groin and leg with blood. Pulsations of the femoral artery can be felt in the groin at the crease between the abdomen and thigh.

• **Dorsalis pedis arteries.** Pulsations of the dorsalis pedis, an artery in the foot, can be felt on the top surface of the foot on the big-toe side.

• **Posterior tibial arteries.** The posterior tibial artery travels from the calf to the foot. Pulsations of this artery can be felt posterior to the medial malleolus (ankle bone).

• **Brachial arteries.** The brachial artery is the major artery of the upper arm. Its pulsations can be felt at the front of the elbow (antecubital region) and on the medial arm midway between the shoulder and elbow. The brachial artery is used when determining blood pressure and when assessing a pulse in an infant.

• **Radial arteries.** The radial artery is the major artery of the arm distal to the elbow joint. Its pulsations can be
felt proximal to the thumb on the wrist. It is the artery that is usually assessed when taking a patient’s pulse.

- **Pulmonary arteries.** The pulmonary arteries, which originate at the right ventricle of the heart, carry oxygen-depleted blood to the lungs, where the blood is oxygenated and returned to the heart for circulation throughout the body. Note: The pulmonary arteries are the only arteries that carry deoxygenated, or oxygen-depleted, blood.

  **The Arterioles.** The arteries are smaller the farther they are from the heart. Each eventually branches into an arteriole, the smallest kind of artery. The arterioles carry blood from the arteries into the capillaries.

  **The Capillaries.** A tiny blood vessel that connects an arteriole to a venule, a capillary has walls that allow for the exchange of gases, nutrients, and waste at the cellular level (Figure 7-26b). All fluid, oxygen, and carbon dioxide exchange takes place between the blood and tissue cells through the walls of the capillaries in all parts of the body.

  In the lungs, oxygen moves out of the alveoli and into the alveolar capillaries while carbon dioxide moves out of the alveolar capillaries and into the alveoli. The carbon dioxide is then blown off through exhalation. In the tissue capillaries throughout the body, the movement of oxygen and carbon dioxide is opposite to that of the alveolar capillaries. Oxygen moves out of the tissue capillaries and into the cells while carbon dioxide and other wastes move out of the cells and into the tissue capillaries. The carbon dioxide and other wastes are then carried through the circulatory system back to the lungs where the alveolar gas exchange and blowing off of carbon dioxide takes place.

  **The Venules.** The smallest branch of the veins, a venule, is connected to the distal ends of capillaries. Blood that has been depleted of oxygen flows from the capillaries into the venules, from which it is transported into larger veins.

  **The Veins.** A vein carries blood back to the heart (Figure 7-26c). All veins except the pulmonary veins (see description that follows) carry oxygen-depleted blood. The major veins include the venae cavae and the pulmonary veins.

**PATHOPHYSIOLOGY PEARLS**

Unlike arteries, veins have valves that keep blood from flowing backward and help in moving the blood forward.

The **venae cavae** carry oxygen-depleted blood back to the right atrium, where it begins circulation through the heart and lungs. The **superior vena cava** enters the top of the right atrium, carrying oxygen-depleted blood from the upper body. The **inferior vena cava** enters the bottom of the right atrium, carrying oxygen-depleted blood from the lower body.

The **pulmonary veins** carry oxygen-rich blood from the lungs to the left atrium. They are the only veins that carry oxygenated blood.

**Composition of the Blood**

Blood is composed of red blood cells, white blood cells, platelets, and plasma.

- **Red blood cells.** The red cells give the blood its color, carry oxygen to the body cells, and carry carbon dioxide away from the cells. Hemoglobin on the surface of the red blood cell is responsible for carrying oxygen molecules and carbon dioxide. The oxygen and carbon dioxide molecules are carried on different sites on the hemoglobin molecule.

- **White blood cells.** The white cells (several types exist) are part of the body’s immune system and help to defend against infection.

- **Platelets and other clotting factors—Platelets and other clotting factors are essential to the formation of blood clots, necessary to stop bleeding.

- **Plasma.** This is the liquid part of the blood, which carries blood cells and transports nutrients to all tissues. The plasma also transports waste products to organs where they can be excreted from the body. A minute amount of oxygen is dissolved in plasma and transported throughout the body. A larger amount of carbon dioxide is carried by the plasma to the lungs for elimination.

**PATHOPHYSIOLOGY PEARLS**

Plasma contains large molecules of albumin that help keep the water portion of the plasma from leaking outside of the vessel.

**Physiology of Circulation**

Two ways of determining the adequacy of circulation are by assessing the pulse and by assessing the blood pressure.

When the left ventricle contracts, sending a wave of blood through the arteries, the pulse, or wave of propelled blood, can be felt at various points called pulse points. Simply, the pulse can be felt at the point where an artery passes over a bone near the skin surface. The pulse is a measure of the effectiveness of the left ventricle as a pump and also provides information about the volume of blood being ejected by the left ventricle and being carried in the arteries.

The central pulses are the carotid and femoral—located centrally, closer to the heart. The peripheral pulses are the radial, brachial, posterior tibial, and dorsalis pedis—located on the periphery of the body, farther from the heart. These pulses can be felt at the locations described earlier. An apical pulse is felt on the left side of the chest over the left ventricle. The pulse being felt is from the mechanical contraction of the left ventricle; however, since you are only feeling the mechanical contraction of the heart and not the pressure wave of blood, it does not provide an assessment of the effectiveness of the heart or blood volume. An apical pulse simply indicates that the heart is contracting. If a patient has lost a significant amount of blood, the apical pulse will still be felt since the heart is still producing a mechanical contraction.
However, the radial or carotid pulses would feel weak or may even be absent because the amount of blood being ejected by the left ventricle would be reduced.

**Blood pressure** is the force exerted by the blood on the interior walls of the arteries. The **systolic blood pressure** is exerted against the walls of the arteries when the left ventricle contracts. The **diastolic blood pressure** is exerted against the walls of the arteries when the left ventricle is at rest, or between contractions. The systolic blood pressure measures the effectiveness of the pumping function of the left ventricle. The diastolic blood pressure measures the resistance in the arteries between contractions. The resistance is related to the vessel diameter. As the vessel diameter gets smaller, the resistance in the vessel increases. An increase in resistance will increase the diastolic blood pressure. Likewise, a decrease in resistance will decrease the diastolic blood pressure. If you have a patient whose vessels are dilating (the diameter is getting larger), his diastolic blood pressure would decrease.

Another type of pressure found inside the vessel is hydrostatic pressure. **Hydrostatic pressure** is the force exerted on the inside of the vessel walls as a result of the blood pressure and volume (Figure 7-27). A significant increase in hydrostatic pressure may cause the blood in the capillaries to force fluid through the capillary wall. Basically, the capillaries begin to leak fluid, which is typically water and not whole blood. This may produce **edema**, which is swelling occurring in the tissues. If the capillaries in the lungs are leaking, the fluid will collect between the alveoli and capillary. This will force the alveoli farther away from the capillary, making gas exchange more difficult and less effective.

**Perfusion** is the delivery of oxygen, glucose, and other nutrients to the cells of all organ systems, and the elimination of carbon dioxide and other waste products, which results from the constant adequate circulation of blood through the capillaries (Figure 7-28).
Shock, or hypoperfusion, is the insufficient supply of oxygen and other nutrients to some of the body’s cells and the inadequate elimination of carbon dioxide and other wastes that result from inadequate circulation of blood. It is a state of profound depression of the vital processes of the body. (Detailed information will be found in Chapter 15, “Shock and Resuscitation.”)

**Transport of Gases in the Blood**

The two most important gases the EMT is concerned with are oxygen and carbon dioxide. Cells require oxygen to function effectively and survive. Carbon dioxide is a waste product that must be carried away from the cells and eliminated by the lungs. An effective transport system must be in place to continuously deliver oxygen to the cells and eliminate carbon dioxide.

Oxygen is carried in the blood in two ways, whereas carbon dioxide is carried in three ways. Oxygen is attached to hemoglobin and dissolved in plasma. About 97 percent of the oxygen carried in the blood is attached to the hemoglobin molecule, which is on the surface of the red blood cell. The remaining 3 percent, not enough to survive on alone, is dissolved in the blood plasma.

Carbon dioxide is transported in the blood as bicarbonate, attached to hemoglobin, and dissolved in plasma. Approximately 70 percent of carbon dioxide is carried in the blood in the form of bicarbonate. The bicarbonate is formed when the carbon dioxide molecule enters the red blood cell and combines with water. The bicarbonate that results leaves the red blood cell and circulates in the blood. When the bicarbonate reaches the lungs, it re-enters the red blood cell, combines with hydrogen, and dissociates into carbon dioxide and water. The carbon dioxide leaves the red blood cell and is blown off by the lungs. Another 23 percent of carbon dioxide attaches to hemoglobin on the surface of the red blood cell. It attaches at a different site than the site where oxygen was attached. Once the blood reaches the lungs, the hemoglobin–carbon dioxide bond is broken and the carbon dioxide enters the alveoli and is exhaled from the lungs. Only 7 percent of carbon dioxide is carried in the blood dissolved in the plasma.

The transport of oxygen and carbon dioxide in the blood can be disrupted in a number of ways, for example, a problem in gas exchange in the alveoli or at the level of cells, an inadequate volume of blood, or ineffective pumping by the heart. The disruption could leave cells without an adequate supply of oxygen and/or could result in a dangerous buildup of carbon dioxide.

**Cell Metabolism**

Cells require energy to survive. The main source of energy is glucose (a simple sugar molecule) that is metabolized inside the cell. In the ideal state, glucose metabolism occurs with adequate amounts of oxygen present. The metabolized glucose provides large amounts of energy for the cells to use. The final by-products of glucose metabolism are water and carbon dioxide. The carbon dioxide is transported away from the cell in one of the methods previously discussed and blown off by the lungs. This kind of metabolism is known as aerobic metabolism. Aerobic means “with oxygen.” Metabolism refers to chemical and physical changes that take place within the cells.

If oxygen is not available when the cell is metabolizing glucose, very little energy is produced for the cell and the end product is acid. Acid is bad for the body if it accumulates. This process of metabolizing glucose without producing much energy is known as anaerobic metabolism, anaerobic means “without oxygen.” If a patient is losing blood and very little oxygen is being delivered to the cells, very little energy is being produced. This may be seen in the patient who appears quiet and calm at the scene. Because of poor perfusion, he doesn’t have enough energy to scream and complain of his injuries. Such patients are those that you should assess first and be more concerned about than the patient who is screaming about his fractured arm with the bone protruding through the skin. The patient who has enough energy to yell and scream is likely getting enough oxygen and glucose to his cells and is producing adequate energy.

**The Nervous System**

The nervous system (Figure 7-30) controls the voluntary and involuntary activity of the human body. It enables the individual to be aware of and react to the environment. It also coordinates the responses of the body to stimuli and keeps body systems working together. Nerves carry impulses from tissues and organs to the nerve centers, and from nerve centers to other tissues and organs.

The basic functions of the nervous system are:

- Controlling and maintaining a conscious and aware state
- Transmitting sensory stimuli to the brain for interpretation
- Controlling motor function and transmitting motor impulses to muscle for voluntary and involuntary movement
- Controlling body functions through the autonomic nervous system

**Structural Divisions of the Nervous System**

The nervous system is divided into two main structural divisions: the central nervous system and the peripheral nervous system.

The central nervous system consists of the brain, which is located within the cranium, and the spinal cord, which is located within the spinal column (Figure 7-30). The three layers of protective membranes enclosing both the brain and the spinal cord are the meninges. In addition, nature provides a cushion of fluid around and within the brain and spinal cord called cerebrospinal fluid. It is formed and circulated constantly, with part perpetually reabsorbed into the brain’s venous blood.
Nervous System

Coordinates body functions

Brain

Transmits messages to and from the brain

Spinal cord

Transmit messages to and from the central nervous system

Nerves

CENTRAL NERVOUS SYSTEM

PERIPHERAL NERVOUS SYSTEM

FIGURE 7-29 The nervous system.
The brain, which is the control center of the nervous system, is probably the most highly specialized organ in the body. It weighs about 3 pounds in the average adult, is richly supplied with blood vessels, and requires considerable oxygen to perform effectively. The brain does not store glucose and requires a constant supply. It has three main subdivisions: the cerebrum, the cerebellum, and the brainstem. A smaller subdivision of the brain, the pons, acts as a bridge that connects the three.

- **The cerebrum.** The outermost portion of the brain, the cerebrum occupies nearly all the cranial cavity. It controls specific body functions, such as sensation, thought, and associative memory. It also initiates and manages motions that are under the conscious control of the individual.

- **The cerebellum.** Also called the “small brain,” the cerebellum is located in the posterior and inferior aspect of the cranium. It coordinates muscle activity and maintains balance through impulses from the eyes and the ears. Though it cannot initiate a muscle contraction, it can hold muscles in a state of partial contraction.

- **Brainstem.** The brainstem contains the mesencephalon, the pons, and the medulla oblongata. The medulla oblongata consists of three major control centers: the respiratory center, the cardiac center, and the vasomotor center. The respiratory center controls the rate and depth of respiration. The cardiac center is responsible for regulating the heart rate and force of contraction of the ventricles. The blood pressure is controlled by the vasomotor center, which produces dilation (relaxation) and constriction of the blood vessels.

**PATHOPHYSIOLOGY PEARLS**

The brain has a specialized network of capillaries called the blood-brain barrier that allows only some substances, such as glucose, to pass through from the blood into the brain.

The spinal cord is about 18 inches long and is an extension of the brainstem. The major function of the spinal cord is conduction of nerve impulses. Many nerves enter and leave the spinal cord at different levels. These nerves all connect with nerve centers located in the brain or spinal cord.

**The Peripheral Nervous System.** The peripheral nervous system is composed of the nerves located outside the spinal cord and brain. Afferent nerves carry sensory information from the body to the spinal cord and brain. Efferent nerves carry motor information from the brain and spinal cord to the body. Together, they create a complete circuit that permits, for example, the sensation of pain and the reflexive withdrawal from it (Figure 7-31).
Functional Divisions of the Nervous System

The functional divisions of the nervous system are the voluntary nervous system and the autonomic nervous system.

The Voluntary Nervous System. The voluntary nervous system influences the activity of skeletal (voluntary) muscles and movements.

The Autonomic Nervous System. The autonomic nervous system, as its name implies, is automatic. It influences the activities of smooth (involuntary) muscles and glands. It is partly independent of the rest of the nervous system.

The autonomic nervous system is divided into the sympathetic nervous system and the parasympathetic nervous system. These two systems have opposite effects and act in a delicate balance. The sympathetic nervous system is activated when the body is challenged by stressors: trauma, blood loss, fright, and so on. Its actions are commonly known as the “fight-or-flight” response. The parasympathetic nervous system returns body processes to normal or depresses body function. Figure 7-32 illustrates the effects on various organs.

![FIGURE 7-32](image) The effects of the sympathetic and parasympathetic nervous systems on organs.
Consciousness and Unconsciousness

Two components of the nervous system that control consciousness are the cerebral hemispheres and the reticular activating system (RAS). The cerebral hemispheres are the large right and left sides of the cerebrum of the brain. The RAS is not an actual structure but a group of nerves found in the brainstem. The RAS is often referred to as the “wake and sleep center” or “on/off center” because it determines whether the patient remains awake and aware of his surroundings or not. The RAS is continuously transmitting impulses regarding the patient’s surroundings to the brain for constant stimulation and response.

Consciousness. In order for the patient to be in a conscious or awake state, the RAS and at least one cerebral hemisphere must be intact and functioning.

Unconsciousness. If either the RAS or both cerebral hemispheres are damaged or not functioning properly, the patient will no longer be in an awake state, or conscious.

PATHOPHYSIOLOGY PEARLS

When a person is injured, the sympathetic nervous system is triggered and provides an immediate response through the nerves. Within minutes, the body also begins to release hormones, such as epinephrine and norepinephrine, to produce a sustained sympathetic nervous system response.

The Endocrine System

The endocrine system is made up of ductless glands, the body’s regulators (Figure 7-33). Secretions from these glands are called hormones, chemical substances that have effects on the activity of certain organs. Hormones are carried by the bloodstream to all parts of the body, affecting physical strength, mental ability, build, stature, reproduction, hair growth, voice pitch, and behavior. How people think, act, and feel depends largely on these secretions.

The endocrine glands discharge secretions directly into the bloodstream. Good health depends on a well-balanced output of hormones. Endocrine imbalance yields profound changes in growth and serious changes in mental, emotional, physical, and sexual behavior.

The endocrine glands and their functions include the following:

- The thyroid gland, which is located in the anterior neck, regulates metabolism, growth and development, and the activity of the nervous system.
- The parathyroid glands, behind the thyroid, produce a hormone necessary for the metabolism of calcium and phosphorus in the bones.
- The adrenal glands, which sit atop the kidneys, secrete epinephrine (adrenaline) and norepinephrine, postpone muscle fatigue, increase the storage of sugar, control kidney function, and regulate the metabolism of salt and water.
- The gonads (ovaries and testes) produce the hormones that govern reproduction and sex characteristics.

- The islets of Langerhans, which are in the pancreas, make insulin, which allows glucose (sugar) to enter cells, and also produce glucagon, a hormone that raises the glucose level in the blood.
- The pituitary gland, which is at the base of the brain, is considered to be the “master gland.” It regulates growth, the thyroid and parathyroid glands, the pancreas, the gonads, metabolism of fatty acids and some basic proteins, blood sugar reactions, and urinary excretion.

Epinephrine and Norepinephrine

As just noted, epinephrine, also known as adrenaline, and norepinephrine are two hormones secreted by the adrenal gland. These hormones produce many of the signs and symptoms seen in patients when the sympathetic nervous system is stimulated. In order to understand the signs and symptoms that are produced, you must first understand the basics of the four effects—alpha1, alpha2, beta1, and beta2—activated by these hormones.

- Alpha1 effects cause the vessels to constrict (vasoconstriction). The vessels in the skin are significantly affected by alpha1. When the vessels in the skin constrict, the blood is shunted to the core of the body. The warm red blood is no longer located in great quantities in the skin. This causes the skin to become cool and pale (white looking). Alpha1 stimulation also causes the sweat glands to release sweat. This causes the skin to become moist, or clammy.
- Alpha2 effects are thought to regulate the release of alpha1.
- Beta1 effects all relate to the heart. They increase the heart rate, increase the force of cardiac contraction, and speed up the electrical impulse traveling down the heart’s conduction system.
- Beta2 effects cause smooth muscle to dilate, especially in the bronchioles and in some vessels.

Epinephrine and norepinephrine are the two primary hormones secreted by the sympathetic nervous system. The hormone epinephrine has all four properties (alpha1, alpha2, beta1, and beta2). Thus, when it is secreted by the adrenal gland or if it is administered to a patient, you would expect all of the actions just listed to occur and to see the signs related to these actions. Epinephrine is used to treat patients with severe allergic reactions to combat the problems found in the condition, primarily vasodilation and bronchoconstriction.

Norepinephrine causes primarily alpha1 and alpha2 effects plus trace amounts of beta1 and beta2 activity. Thus, the majority of the effects of norepinephrine are seen in the blood vessels and skin (pale, cool, and clammy).

Recognizing these signs and understanding how they are produced may lead you to suspect the presence of some conditions much earlier, affording you the time to provide your patient better care. For example, in a

**Endocrine System**

- **Pineal Gland**
  - Regulates circadian rhythm

- **Pituitary Gland**
  - Regulates many other endocrine glands

- **Thyroid Gland**
  - Regulates metabolic rate
  - Regulate blood calcium level

- **Parathyroid Glands**
  - Regulate water and electrolyte levels

- **Adrenal Glands**
  - Regulate metabolic rate
  - Regulate blood calcium level

- **Thymus Gland**
  - Development of immune system

- **Ovaries**
  - Regulate female reproductive system

- **Pancreas**
  - Regulates blood sugar levels

- **Testes**
  - Regulate male reproductive system

**Figure 7-33** The endocrine system.
patient who is losing blood, the body will try to compensate by releasing epinephrine and norepinephrine. Being able to recognize the signs and understand why they are occurring may help you to suspect the blood loss much earlier and treat the patient more aggressively. Also, you will be administering or assisting with the administration of drugs containing these properties.

The Integumentary System (Skin)

All the various tissues, organs, and systems that make up the human body are separated from the outside environment by the skin, which is also known as the integumentary system (Figure 7-34 ■). The skin has the following functions:

- Protecting the body from the environment, bacteria, and other foreign organisms
- Regulating the temperature of the body
- Serving as a receptor for heat, cold, touch, pain, and pressure
- Aiding in the regulation of water and electrolytes (sodium and chloride)

The skin has three layers: the epidermis, the dermis, and a subcutaneous layer. The epidermis, or outermost layer of skin, is actually composed of four layers of cells. The outer two layers are dying and dead cells that are sloughed off as new cells replace them. The skin’s pigmentation—the melanin—is located in the deepest layers of the epidermis.

The dermis, or second layer of the skin, is much thicker than the epidermis. It contains the vast network of blood vessels that supply the skin as well as the hair follicles, sweat glands, oil glands, and sensory nerves. Composed of dense connective tissue, the dermis gives the skin its elasticity and strength.

Just below the dermis is a layer of fatty tissue called the subcutaneous layer, or subcutaneous connective tissue. It varies in thickness, depending on what part of the body it covers. Subcutaneous tissue of the eyelids, for example, is extremely thin, but that of the abdomen and buttocks is thick.

The four accessory structures of the skin are the nails, hair, sweat glands, and oil glands.

The Digestive System

Basic Anatomy

The digestive system (Figure 7-35 ■) is composed of the alimentary tract (the passage through which food travels) and the accessory organs (organs that help prepare food for absorption and use by tissues of the body). The main functions of the digestive system are to ingest and carry food so that absorption can occur and waste can be eliminated.

The abdominal cavity contains all the major organs of the digestive system except for the mouth and the esophagus. The esophagus is a flexible tubelike structure located posterior to the trachea and is responsible for carrying food from the mouth to the stomach.

The stomach, a large, hollow organ, is the main organ of the digestive system. While digestion actually begins in the mouth, where saliva begins to break down foods, the majority of digestion takes place in the stomach, which secretes gastric juices that begin
Digestive System

- **salivary glands**: Produces saliva
- **oral cavity**: Ingests, chews, and swallows food
- **esophagus**: Transports food to the stomach
- **stomach**: Secretes acid and mixes food to start digestion
- **pancreas**: Secretes digestive enzymes and buffers
- **liver & gallbladder**: Produces and stores bile
- **small intestine**: Digests and absorbs nutrients
- **colon**: Reabsorbs water and stores feces

**FIGURE 7-35** The digestive system.
converting ingested foods to a form that can be absorbed and used by the body.

- **The pancreas** is a flat, solid organ that lies just inferior and posterior to the stomach. It secretes pancreatic juices that aid in the digestion of fats, starches, and proteins. The islets of Langerhans, located in the pancreas, produce the insulin that regulates the amount of sugar in the bloodstream.

- **The liver**, the largest solid organ in the abdomen, lies immediately beneath the diaphragm in the right upper quadrant of the abdominal cavity. The liver produces bile, which aids in the digestion of fat. It stores sugars until they are needed by the body. It also produces components necessary for immune function, blood clotting, and the production of plasma. Finally, the toxic substances produced by digestion are rendered harmless in the liver.

- **The spleen** is a solid organ located in the left upper quadrant of the abdominal cavity. It helps in the filtration of blood and, because it contains a dense network of blood vessels, serves as a reservoir of blood the body can use in an emergency such as hemorrhage. Although it lies among the digestive organs, the spleen has no digestive function.

- **The gallbladder** is a hollow pouch. Part of the bile duct leading from the liver, the gallbladder acts as a reservoir for bile. When food enters the small intestine, contractions are stimulated that empty the gallbladder into the small intestine, where the bile aids in the digestion of fats.

- **The small intestine** is made up of the duodenum, jejunum, and ileum. It receives food from the stomach and secretions from the pancreas and liver. Digestion of food continues in the small intestine, where food is completely broken down into a form that can be used by the body. Nutrients are absorbed through the walls of the small intestine and circulated through the bloodstream to all parts of the body.

- **The large intestine** is also called the colon. The parts of food that cannot be absorbed by the body are passed as waste products from the small intestine to the large intestine. As these waste products move through the large intestine, their water is absorbed. What remains is the stool that is then passed through the rectum and the anus.

### Digestive Process

Digestion consists of two processes—one mechanical and the other chemical. The mechanical process includes chewing, swallowing, *peristalsis* (the rhythmic movement of matter through the digestive tract), and *defecation* (the elimination of digestive wastes). The chemical process of digestion occurs when *enzymes*, or digestive juices, break foods down into simple components that can be absorbed and used by the body. Carbohydrates are converted into glucose (simple sugar), fats are changed into fatty acids, and proteins are converted to amino acids.

### The Urinary or Renal System

The **urinary system** or **renal system** (Figure 7-36) filters and excretes wastes from the blood. It consists of two kidneys, which filter waste from the bloodstream and help control fluid balance; two ureters, which carry the wastes from the kidneys to the bladder; one **urinary bladder**, which stores the urine prior to excretion; and one **urethra**, which carries the urine from the bladder out of the body. The kidneys also play an important role in blood pressure regulation.

The urinary system helps the body maintain its delicate balance of water and various chemicals in the proportions needed for health and survival. During the process of urine formation, wastes are removed from the circulating blood for elimination, and useful products are returned to the blood. Kidney function also helps to maintain a normal acid-base balance in the body.

### The Reproductive System

The **reproductive system** of women and men consists of complementary organs that can function to accomplish human reproduction. The male’s *sperm* and the female’s *ovum* contribute the genes that determine the hereditary characteristics of an offspring. Combination of a single sperm with a single ovum forms a fertilized ovum, which can grow into an *embryo*, then into a *fetus*, and finally into a newborn baby.

The reproductive system of the male (Figure 7-37) includes two testes, a duct system, accessory glands (including the *prostate gland*), and the *penis*. The testes are responsible for the production of testosterone, the primary male hormone.

The female reproductive system (Figure 7-38) consists of two ovaries, two *fallopian tubes*, the *uterus*, the *vagina*, and the *external genitals*. The ovaries produce and secrete estrogen and progesterone, the primary female hormones. The female reproductive structures and function will be discussed in more detail in Chapter 23, “Abdominal, Hematologic, Gynecologic, Genitourinary, and Renal Emergencies,” and Chapter 37, “Obstetrics and Care of the Newborn.”

### MEDICAL TERMINOLOGY

**Medical terminology** refers to the specialized language used in all fields of medicine. To communicate effectively with other members of the health care team, you must have a basic understanding of medical terminology. In addition, knowing the basic components of medical terms will assist you in understanding the terminology used throughout this textbook, classroom lectures, continuing education sessions, and any future medical education you might pursue. Finally, using medical terminology properly will help you develop a more professional and competent presentation.
Urinary System

- **Kidney**: Filters blood and produces urine.
- **Ureter**: Transports urine to the bladder.
- **Urinary Bladder**: Stores urine.
- **Male Urethra**: Transports urine to exterior.
- **Female Urethra**: Transports urine to exterior.

*FIGURE 7-36* The urinary system.
Male Reproductive System

- **testes**: Produces sperm and secretes testosterone.
- **epididymis**: Stores sperm.
- **vas deferens**: Transports sperm to urethra.
- **seminal vesicles**: Secretes fluid for semen.
- **prostate gland**: Secretes fluid for semen.
- **bulbourethral gland**: Secretes fluid for semen.
- **penis**: Delivers semen during intercourse.

**FIGURE 7-37** The male reproductive system.
Female Reproductive System

- **breast**: Produces milk
- **uterus**: Site of development of fetus
- **fallopian tube**: Transports ovum to uterus
- **ovary**: Produces ova and secretes estrogen and progesterone
- **vagina**: Receives semen during intercourse; birth canal
- **vulva**: Protects vaginal orifice and urinary meatus

**FIGURE 7-38** The female reproductive system.
Medical Words and Word Parts

Medical terminology may look complex, but the way medical words are constructed is simple. Medical words are made of word parts, and there are only three kinds of word parts: combining forms, suffixes, and prefixes. The ability to break down a medical word into its parts will drastically improve your ability to understand its meaning.

As just noted, every medical word contains a **combining form**. The combining form is the foundation of the word and gives the word its essential meaning. A combining form has two parts: a **root** (which contains the medical meaning) and a **combining vowel**. The combining vowel (usually a, e, or i) helps join the root to another word part and makes the resulting whole word pronounceable. An example is the combining form **cardi/o-**:

```
+---+---+
<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>
+---+---+
| root| slash| combining vowel| hyphen |
```

A combining form always ends with a hyphen to show that it is a word part, not a complete word. The hyphen—and sometimes the combining vowel—is deleted when the combining form is joined with a prefix, another combining form, and/or a suffix to make a word.

**combining form + suffix = word**

**cardi/o- + -logy = cardiology**

(heart) + (study of) = (study of the heart)

**prefix + combining form + suffix = word**

**peri- + cardi/o- + -um = pericardium**

(around) + (heart) + (structure) = (structure that surrounds the heart)

Some medical words contain more than one combining form.

**combining form + combining form + suffix = word**

**my/o- + cardi/o- + -al = myocardial**

(muscle) + (heart) + (pertaining to) = (pertaining to heart muscle)

In the prior examples, the combining form **cardi/o-** refers to the heart. Other common combining forms are **pulmon/o-**, referring to the lungs; **angi/o-**, referring to the blood vessels; **bronch/o-**, referring to the bronchi of the lower airway; and **cerebr/o-**, referring to the cerebrum of the brain.

A **suffix** is a word part added to the end of a combining form that modifies or gives additional or specific meaning to the combining form. By adding a suffix to one of the combining forms just mentioned, a new medical word is produced. As an example, if the suffix **-itis**, which means “inflammation,” is added to the combining form **bronch/o-**, it becomes the medical word **bronchitis**. By breaking down the meaning of the combining form and suffix, it is easy to define **bronchitis**.

Several suffixes may share the same meaning. The suffixes **-ac, -al, -ary, -eal, -ic, and -ous** all mean “pertaining to.” When one of these suffixes is added to a combining form, it typically makes the word an adjective. For example, the combining form **hepat/o-** means “liver.” When the suffix **-ic** is added to **hepat/o-**, it becomes **hepatic**, which means “pertaining to the liver.”

**combining form + suffix = word**

**hepat/o- + -ic = hepatic**

(liver) + (pertaining to) = (pertaining to the liver)

As noted earlier, some medical terms may contain more than one combining form. An example is **laryngotraceobronchitis**. At first, you may think this word is confusing and hard to understand, not to mention unpronounceable. However, by breaking the term into the combining forms and suffix, it becomes easy to understand—and even to pronounce.

**combining form + combining form + combining form + suffix = word**

**laryng/o- + trache/o- + bronch/o- + -itis = laryngotraceobronchitis**

(larynx) + (trachea) + (bronchus) + (inflammation of) = (inflammation of the larynx, trachea, and bronchi)

**prefix** is a word part that comes before a combining form. The prefix modifies the combining form or forms, often indicating direction, time, or orientation. In the medical word **endotracheal**, the prefix **endo-** means “within.” An endotracheal tube is a tube that lies within the trachea.

**prefix + combining form + suffix = word**

**endo- + trache/o- + -al = endotracheal**

(within) + (trachea) + (pertaining to) = (pertaining to something within the trachea)

The easiest way to learn prefixes, combining forms, and suffixes is to memorize them; in fact, memorizing word parts and their meanings is useful, because they will be encountered in many medical words and always have the same meaning. However, memorizing is not the easiest way to learn whole medical words. Instead, medical words can be easily understood by breaking them down into, and knowing the meanings of, the individual prefixes, combining forms, and suffixes. It is not only impossible to memorize all of the medical words you will need to know, it is not necessary, because you can decode any medical word by separating it into its recognizable parts.

Refer to Table 7-1 for a few medical words that you will encounter when reading this text and an example of how each can be easily broken down and understood.

Refer to Table 7-2 for common combining forms, Table 7-3 for common prefixes, and Table 7-4 for common suffixes. These are not all-inclusive lists. It is strongly

SUMMARY

It is essential to develop a foundation of knowledge of basic anatomy and physiology in order to better understand signs and symptoms patients will present with and the reasons for and effects of certain treatments you will administer. This basic understanding will assist you in determining what body systems are affected by an injury or illness and whether there are any potential life threats to that system. Also, knowing how the systems are interrelated will assist you in determining what areas of the body to assess when a patient has a particular complaint or injury.

Anatomical terms, planes, and lines will help you to better describe patient positioning and injuries to the body. Along with medical terminology, it will increase your ability to communicate effectively and professionally with other health care providers.

There are several body systems of which you must have a basic understanding: musculoskeletal, respiratory, circulatory, nervous, endocrine, integumentary (skin), digestive, urinary, and reproductive systems.

Case Study Follow-up

Scene Size-up

You have been dispatched to the scene of a 38-year-old woman who was burned when the fuel for a model airplane ignited. By the time you arrive, the fire has been extinguished and the fuel and airplane no longer pose a threat.

Patient Assessment

Your general impression is that the patient is experiencing extreme pain from burns to her right arm and the right side of her head. When you question the patient, she responds appropriately with her name—Sherry Washington—and is able to describe what happened. Her airway and breathing are adequate. You assess circulation and start oxygen therapy before proceeding with the secondary assessment and care.

Upon examining the injury sites, you find that the entire right arm from the elbow to the fingertips has been severely charred from the burning fuel. The burns to the head are minor but fairly extensive, involving the right side of Ms. Washington’s face and singeing to the hair, and you notice some swelling of the mucous membranes in the mouth and singeing of the nasal hair. Since burns to the mouth and nose can have serious effects on the airway and breathing, you are particularly careful to assess burns to her mouth and upper airway.

Pupils are equal and reactive to light. There are no other injuries noted to the head or neck. Breath sounds are equal bilaterally and the patient denies shortness of breath. You inspect the entire body for evidence of other burns. You find present pulses to all extremities, and the patient is able to move her extremities well.

While performing the physical exam, you also ask questions to gather the patient’s history. The information you elicit is consistent with the burn injury. There is no other significant medical history.

Your partner readies the wheeled stretcher while you record the patient’s vital signs. You find that blood pressure and heart rate are both slightly high while rate and depth of breathing are normal.

You gently place sterile burn sheets on the injury sites and try to help the patient relax as you and your partner prepare her for transport. You place her on the cot in a Fowler’s position, which she finds is comfortable and helps her to breathe easily.

En route to the hospital you reassess the patient’s mental status, airway, respiration, and circulation, and ensure that the burn sheets are properly protecting the burned skin. Ms. Washington remains alert. You reassess vital signs and record your findings.

Communication and Documentation

You notify the hospital en route, describing the types and locations of the burns. You tell the staff that there is a full-thickness burn (through all layers of the skin) originating at the right elbow joint, which extends inferiorly and circumferentially to the distal fingers. The burn to the skull appears to be a superficial burn that involves the right cranium and face. The facial burn involves the lateral aspect of the right mandible, maxilla, and zygomatic arch. The emergency physician reminds you to stay alert to possible airway compromise from upper airway swelling as a result of the burns to the face.

When you arrive at the hospital, Ms. Washington is still alert and suffering severe pain but in no severe respiratory distress. You give a verbal report to the emergency department staff and help transfer the patient to a hospital bed. You and your partner then complete theprehospital care report, restock the ambulance, and prepare for another call.

Reflecting on this call, you are able to take pride in your ability to communicate clearly with the emergency department staff, and to document Ms. Washington’s injuries in your prehospital care report, using correct anatomical terminology.
IN REVIEW

1. Describe the following six positions: normal anatomical position, supine, prone, lateral recumbent, Fowler's, and Trendelenburg.

2. Define the following five descriptive terms: midline, midclavicular line, midaxillary line, plantar, and palmar. Also define the following five terms and name and define the opposite of each term: anterior, superior, dorsal, lateral, and distal.

3. Briefly describe the anatomy and physiology of the musculoskeletal system.

4. Briefly describe the anatomy and physiology of the respiratory system.

5. Briefly describe the anatomy and physiology of the circulatory system.

6. Identify the central and peripheral pulse points and their locations.

7. Define shock (hypoperfusion).

8. Briefly describe the anatomy and physiology of the nervous system.

9. Briefly describe the anatomy and physiology of the endocrine system.

10. Briefly describe the anatomy and physiology of the skin.

11. Briefly describe the anatomy and physiology of the digestive system.

12. Briefly describe the anatomy and physiology of the urinary or renal system.

13. Briefly describe the anatomy and physiology of the reproductive system for both the male and female.

CRITICAL THINKING

You arrive on the scene and find a 23-year-old male patient who has several stab wounds to the neck, the front of the chest on the right side, and the abdomen. He is screaming in pain. His breathing is 28 per minute and his radial pulse is weak and rapid. His skin is pale, cool, and clammy. His BP is 88/68 mmHg.

1. What body systems do you suspect could be injured by the knife wounds?

2. Pick a knife wound location on this patient’s body and provide a brief description of the injury using medical terminology and anatomical terms as you would use them in your written EMS report.

3. What is causing the elevated heart rate?

4. What is causing the skin to be pale, cool, and clammy?

5. What is the significance of the systolic and diastolic blood pressure?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Pathophysiology**

**COMPETENCY •** Applies fundamental knowledge of the pathophysiology of respiration and perfusion to patient assessment and management.

**OBJECTIVES •** After reading this chapter, you should be able to:

8-1. Define key terms introduced in this chapter.
8-2. Explain the importance of understanding basic pathophysiology.
8-3. Differentiate between the processes of aerobic and anaerobic cellular metabolism, including explanations of:
   a. The amount of ATP produced
   b. Removal of by-products of metabolism
8-4. Describe the consequences of failure of the cellular sodium/potassium pump.
8-5. Explain the concept of perfusion, including the physical and physiological components necessary to maintain perfusion.
8-6. Describe the composition of ambient air.
8-7. Apply Boyle’s law to ventilation.
8-8. Explain how changes in compliance of the lungs and chest wall and changes in airway resistance affect ventilation.
8-9. Describe the consequences of loss of contact between the parietal and visceral pleura.
8-10. Explain the concept of minute ventilation.
8-11. Differentiate between minute ventilation and alveolar ventilation.
8-12. Describe the roles of chemoreceptors, lung receptors, and the nervous system in the control of ventilation.
8-13. Explain the concept of the ventilation/perfusion (VQ) ratio.
8-14. Describe the transport of oxygen and carbon dioxide in the blood.
8-15. Explain the exchange of gases across the alveolar/capillary membrane and the exchange of gases between capillaries and cells.
8-16. Describe the composition of blood, including the function of plasma and the formed elements.
8-17. Explain the effects of changes in hydrostatic pressure and plasma oncotic pressure on the movement of fluid between the circulatory system and interstitial spaces.
8-18. Discuss factors that affect cardiac output, including heart rate, stroke volume, myocardial contractility, preload, and afterload.
8-19. Describe the concept of systemic vascular resistance and its relationship to blood pressure and pulse pressure.
8-20. Summarize the local, neural, and hormonal factors that regulate blood flow through the capillaries.
8-21. Explain the regulation of blood pressure by baroreceptors and chemoreceptors.
8-22. Explain the relationship between ventilation, perfusion, and cellular metabolism.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

INTRODUCTION

One of the most fundamental purposes of emergency care is maintaining adequate perfusion of the body cells to ensure continuous delivery of oxygen and glucose and removal of waste by-products. These basic molecules—oxygen and glucose—are necessary for normal cell metabolism and function. Many illnesses and injuries can disturb the delivery of oxygen and glucose and removal of waste by-products. Understanding these disturbances will allow you to better recognize and explain why certain signs and symptoms occur and to comprehend the emergency care you will need to provide to the patient.

CELLULAR METABOLISM

Cellular metabolism, also known as cellular respiration, is the process in which, normally, the body cells break down molecules of glucose to produce energy for the body. There are two types of cellular metabolism, aerobic and anaerobic, which will be discussed in the following sections. Which of these two types of cellular metabolism occurs is based on whether there is an effective and continuous delivery of oxygen and energy sources, or fuel. Glucose is the primary fuel, and oxygen is the primary catalyst for metabolism within the cell.

Aerobic Metabolism

Aerobic metabolism is the breakdown of molecules such as glucose through a series of reactions that produce energy within the cells in the presence of oxygen. (The term aerobic means “with oxygen.”) When glucose crosses the cell membrane, it is broken down into pyruvic acid molecules. This process, known as glycolysis, occurs in the fluid portion of the cell (cytosol) and does not require oxygen. However, glycolysis releases only a small amount of adenosine triphosphate (ATP). ATP is an energy source that is required by the cell to release more energy and a necessity for cells to carry out certain functions, such as contraction of muscles. When oxygen is available, the reaction continues inside the mitochondria of the cell where the process releases a much larger amount of energy (ATP). This large amount of energy is necessary for normal cell function (Figure 8-1a).

Other by-products of aerobic metabolism include heat, carbon dioxide, and water. The heat produced is used to maintain a normal body core temperature. As you would expect, an increased metabolism results in increased body core temperature. The carbon dioxide produced by metabolism is transported in the blood and blown off in the exhalation phase of normal respiration. An increase in metabolism results in an increase in the respiratory rate to eliminate the extra carbon dioxide. The water produced by metabolism is reabsorbed and used within the body or excreted. Thus, all of the...
products of aerobic metabolism are either used by the body or eliminated without causing any harm to the cells or to the patient, and a high amount of energy is made available to allow for normal body functions.

**Anaerobic Metabolism**

Anaerobic metabolism is the breakdown of molecules in the cells *without the presence of oxygen*. (The term anaerobic means “without oxygen.”) Just as with aerobic metabolism, glucose crosses the cell membrane and normal glycolysis occurs with the production of pyruvic acid and the release of a small amount of ATP. Without the availability of oxygen, however, the pyruvic acid is not able to enter the next phase of metabolism and is converted to lactic acid. So the by-products of anaerobic metabolism are lactic acid and a small amount of ATP (Figure 8-1b).

If the acid is allowed to accumulate, it produces an acidic environment which may disturb its function and stability. High acid levels inactivate enzyme function, disrupt cell membranes, and ultimately lead to cell death. In addition, the cell has very little energy to perform its normal functions. Thus, an inadequate delivery of oxygen and glucose to cells will result in very little energy production, reduced cellular function, and the possibility of cellular damage.

**Sodium/Potassium Pump Failure**

One detrimental effect of anaerobic metabolism or the lack of glucose delivery to cells is related to the function of the sodium/potassium pump. Sodium and potassium are ions, that is, electrically charged molecules. Sodium (chemical symbol Na⁺) is a positively charged ion that is found primarily in the fluid outside the cell, although some sodium is also found inside the cell. It is considered the primary extracellular ion. Potassium (chemical symbol K⁺) is also positively charged and is considered the primary intracellular ion. That is, it is found primarily in the fluid on the inside of the cell but also exists outside the cell. Most body cells, to perform their special functions such as muscle contraction and nerve impulse transmission, require an alternating movement of sodium out of the cells and potassium into the cells, with these in-and-out cycles occurring continuously.

Sodium that is inside a cell wants to stay inside the cell where its concentration is less. (Molecules naturally move from an area of greater concentration to an area of lesser concentration—moving “with the concentration gradient”—not the other way around.) So sodium molecules do not just flow out of the cell; they have to be actively pumped out against the concentration gradient. Potassium, moving with the concentration gradient, is then generally able to enter the cell where it belongs. The sodium/potassium pump constantly exchanges sodium for potassium in a continuous cycle.

For the sodium/potassium pump to work, as with any other pump, energy is required. The energy is in the form of ATP which, as noted earlier, is released through glycolysis, the breakdown of glucose within the cell (Figure 8-2).

If there is a lack of ATP/energy production by cells, as found in poor perfusion states and anaerobic metabolism, the sodium/potassium pump may fail. This would allow sodium to collect on the inside of the cell. As is well known, water follows sodium. So as sodium collects inside the cell, it attracts water. As the water continues to accumulate, the cell swells and eventually ruptures and dies (Figure 8-3). Thus the end result of a lack of energy to run the pump is cell death.

The effect on the cell of failure of the sodium/potassium pump is an example of how a lack of adequate...
delivery of oxygen and glucose to cells can lead to cell death and organ failure. It is also an example of why maintaining delivery of oxygen and glucose to the cells and elimination of waste products from the cells is a fundamental purpose of emergency care for any patient.

**COMPONENTS NECESSARY FOR ADEQUATE PERFUSION**

Perfusion can be described as the delivery of oxygen, glucose, and other substances to the cells and the elimination of waste products from the cells. In order to maintain adequate perfusion, the components of the delivery and removal system must work properly. These components (each of which will be discussed in the following sections) are:

- Composition of ambient air
- Patent airway
- Mechanics of ventilation
- Regulation of ventilation
- Ventilation/perfusion ratio
- Transport of oxygen and carbon dioxide by the blood
- Blood volume
- Pump function of the myocardium
- Systemic vascular resistance
- Microcirculation
- Blood pressure

An alteration in any one of these components may lead to poor cellular perfusion with an inadequate delivery of oxygen or glucose to the cell or inadequate elimination of carbon dioxide and other waste products. Inadequate perfusion can shift cells from aerobic to anaerobic metabolism, reduce the production of energy needed for normal cell function, produce harmful by-products, and allow waste products to accumulate. Therefore, your emergency care will focus on establishing and maintaining each of these components to
ensure continuous adequate cellular perfusion and aerobic metabolism.

As an example, establishing and maintaining a patent (open) airway will allow adequate amounts of oxygen-rich air to enter the alveoli of the lungs. If the airway is not patent, the amount of oxygen-rich air available in the alveoli will be reduced. Blood passing through the adjoining capillaries will pick up less oxygen and will then deliver less oxygen to the cells. If the amount of oxygen is reduced significantly, the cells will shift from aerobic to anaerobic metabolism. Anaerobic metabolism will reduce the amount of ATP (energy) produced for normal cell function and will begin to produce lactic acid as a by-product, both of which will adversely affect normal cell and organ function and may eventually lead to cell and organ death.

### Composition of Ambient Air

The concentration of oxygen in the ambient air will determine the proportion of oxygen molecules that end up in the alveoli to be available for gas exchange with the blood. A lesser proportion of oxygen in the blood means less oxygen for cells to use for metabolism.

Ambient air at sea level contains approximately 79 percent nitrogen, 21 percent oxygen, 0.9 percent argon, and 0.03 percent carbon dioxide. There are trace amounts of other gases. The partial pressures of these gases are found in Table 8-1. The partial pressures of the gases will be discussed later in the chapter.

If the patient is in an environment low in oxygen, such as an enclosed space with toxic gases, the reduced oxygen concentration will result in cellular hypoxia. It is important to ensure that the concentration of oxygen the patient is breathing is at least 21 percent.

Increasing the concentration of oxygen in breathed air will increase the number of oxygen molecules in the alveoli, the blood, and the cells. Thus, one way to improve cellular oxygenation is by increasing the concentration of oxygen in the air breathed in by the patient. This can be achieved by increasing the FiO₂, which is the fraction of inspired oxygen. An FiO₂ is expressed as a fraction or decimal and not a percentage. A patient breathing ambient air that contains 21 percent oxygen would have an FiO₂ of 0.21. A nonrebreather mask can deliver an FiO₂ of approximately 0.95, which is an oxygen concentration of approximately 95 percent. An FiO₂ of 1.0 would be equal to inspiration of a 100 percent oxygen concentration.

An FDO₂ is a fraction of delivered oxygen. The difference between an FiO₂ and an FDO₂ is that the FiO₂ is administered to a patient who is breathing spontaneously and inhaling the air on his own effort, whereas the FDO₂ is delivered by a ventilation device to a patient who is not able to breathe adequately on his own. The concept is the same, though, and FiO₂ is typically used in place of FDO₂. FDO₂ is rarely used. If you are ventilating the patient with a bag-valve-mask device connected to a reservoir with oxygen flowing at 15 lpm, you are likely delivering an oxygen concentration of approximately 95 to 98 percent, or an FDO₂ of 0.95 to 0.98. Both FiO₂ and FDO₂ are numbers you are most likely to encounter when transporting patients from one medical facility to another who are either on a ventilator or require manual ventilation or supplemental oxygen during the transport.

Some toxic gases displace the amount of oxygen in the air and basically suffocate the patient. Other gases, such as carbon monoxide, disrupt the ability of the blood to carry adequate amounts of oxygen to the cells. In either condition, the cells end up hypoxic.

Some toxic gases may not severely reduce the concentration of oxygen in the air or disrupt the ability of the blood to carry oxygen but may interfere with its use by the cell. One example is cyanide poisoning. The patient may be breathing in an adequate percentage of

oxygen, and the oxygen is adequately transported to the cells, but the cyanide prevents the oxygen from being used effectively by the cells. In this case, the alveoli and blood have adequate amounts of oxygen; nevertheless, the cells become severely hypoxic.

**Patency of the Airway**

One of the most basic and important aspects of any emergency care provided is to establish and maintain a patent airway. A patent airway is one that is open and not obstructed by blood, secretions, vomitus, tissue, bone, teeth, or any other substance. Establishing an open airway is typically one of the first steps in emergency care. In some cases, it may be the only care necessary to treat the patient in the prehospital setting. Failure to recognize, establish, or maintain a patent airway—as already noted—will lead to reduced oxygen concentration breathed in, cellular hypoxia, and eventual patient death.

An airway obstruction can occur at several anatomical levels in both the upper and the lower airway including the nasopharynx, oropharynx, posterior pharynx, epiglottis, larynx, trachea, and bronchi (Figure 8-4).

**Nasopharynx**

An obstruction may occur to the nasopharynx by blood, secretions, vomitus, tissue swelling, bone fragments, or other substances. This usually does not pose a major airway problem if the oropharynx remains clear. However, the nasopharynx opens into the pharynx, which leads to the larynx, the trachea, and eventually the lungs. Blood, vomitus, or other substances that occlude the nasopharynx may drain into the pharynx and lead to aspiration or occlusion. Thus, it is important to keep the nasopharynx clear to prevent potential aspiration. In addition, if you are unable to gain access to the oropharynx because of a fractured mandible or clenched teeth, the nasopharynx can be used as an alternative location to establish an airway. Infants are obligate nose breathers; thus it is imperative to keep the nasopharynx clear in these patients.

**Oropharynx and Pharynx**

The oropharynx and pharynx can be obstructed by the tongue, foreign bodies, tissue swelling, hematomas, blood, vomitus, and other substances. Any obstruction must be removed immediately. Liquid substances such as blood or vomitus can easily be aspirated (breathed into the lungs) from the oropharynx and pharynx. Aspirated substances like vomitus may damage the lung tissue or fill the alveoli and interfere with gas exchange. Blockage of airflow in the oropharynx and pharynx or aspiration of liquid substances will lead to a decreased alveolar oxygenation and a reduced delivery of oxygen to cells, leading to cellular hypoxia.
Epiglottis

The epiglottis is a flap of cartilaginous tissue that covers the opening of the larynx, known as the glottic opening, during swallowing. If the epiglottis is injured and swells or becomes inflamed from infection, it can occlude the airway at the level of the larynx. The epiglottis is flexible tissue; thus, it may fall over the glottic opening when the muscles controlling the tongue relax and become flaccid. A jaw-thrust or chin-lift maneuver is designed to lift the epiglottis clear of the glottic opening. If there is obstruction from swelling or inflammation, advanced airway management may be required to establish a patent airway.

Larynx

The larynx is the structure that contains the vocal cords. The anterior portion is composed of the thyroid cartilage, which is the prominent “Adam’s apple” often seen in males. The most inferior portion is the cricoid cartilage, a completely circumferential cartilaginous ring. The adult has a cylindrical airway, and the narrowest portion of the upper airway in the adult is at the level of the vocal cords. A child less than 8 years of age, however, has a cone-shaped airway with the narrowest portion at the cricoid ring.

The larynx can be obstructed by laryngeal spasm, also called laryngospasm, where the vocal cords spasm and close together, which prevents any air from passing through into the trachea. This may result from injury, insertion of mechanical airways, or administration of some medications. A fracture to the larynx may cause the laryngeal structures to lose stability and be drawn inward, creating an obstruction. Any obstruction at the level of the larynx will prevent airflow into the trachea and lungs, leading to a reduced amount of oxygen in the alveoli, which results in poor oxygen levels in the blood and cellular hypoxia.

Trachea and Bronchi

The larynx opens into the trachea, which extends downward and bifurcates at the carina. The carina is located at the second intercostal space (angle of Louis) anteriorly or the fourth thoracic vertebra posteriorly. The trachea is composed of anterior cartilaginous rings that are C-shaped with a soft, flexible muscle on the posterior aspect. The trachea bifurcates into the right mainstem bronchus and left mainstem bronchus. Obstruction of the trachea and bronchi by secretions, blood, vomitus, food particles, objects, tissue, swelling, bone, or other substances blocks airflow to the bronchioles, which supply the alveoli with oxygenated air. This reduces the concentration of oxygen in the alveoli, which in turn reduces gas exchange and the amount of oxygen transported by the blood to the cells, leading to cellular hypoxia.

Respiratory Compromise Associated with Mechanics of Ventilation

The integrity of the thoracic cavity plays an integral role in maintaining normal ventilation. The thoracic cavity is formed by the neck muscles and first two ribs superiorly; diaphragm inferiorly; muscles, ribs, and sternum anteriorly; and muscles, vertebrae, and ribs posteriorly. It is divided by the mediastinum into a right and left hemithorax. The lungs are covered by a pleural lining. The visceral pleura is the innermost lining covering the lung tissue; the parietal pleura is the outermost lining that adheres to the thoracic wall. As discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” these structures are necessary for normal ventilation to occur.

Boyle’s Law Applied to Ventilation

Ventilation is a mechanical process that relies on changes in pressure inside the thorax to move air in and out of the lungs. The alterations in pressure occur as a result of changes to the size of the thorax. Ventilation conforms to Boyle’s law, which states that the volume of gas is inversely proportionate to the pressure. It can be quickly summarized as follows:

An increase in pressure (more positive)
will decrease the volume of gas.

A decrease in pressure (more negative)
will increase the volume of gas.

Increasing the size of a closed container will decrease the internal pressure (create a negative pressure) by creating a partial vacuum. The vacuum may be thought of as “sucking air into the container.” More accurately, it is the higher pressure outside that pushes air into the container, increasing the volume of gas. Conversely, decreasing the size of a container will increase the internal pressure (create a positive pressure) and force air out, decreasing the volume of gas.

By contracting the diaphragm (the muscle that provides approximately 60 to 70 percent of the effort of inhalation) and the external intercostal muscles, the diaphragm moves slightly downward while the ribs are lifted upward and outward. This causes the thorax to increase in size, creating a negative pressure. Normal atmospheric pressure is 760 mmHg at sea level. With the expansion of the thorax immediately prior to inhalation, the pressure inside the chest drops to 758 mmHg. In accordance with Boyle’s law, this negative pressure causes the volume of air inside the chest to increase. Because energy must be expended to contract the muscles, inhalation is considered an active process.

As the parietal pleural lining is pulled upward and outward with the expansion of the chest wall, the serous fluid between the two linings also pulls the visceral lining upward and outward. (This pulling by the serous fluid between the pleural linings is sometimes called a
“water glass” effect, similar to the surface tension created by moisture between the bottom of a glass and the surface the glass is sitting on, which will tend to lift the surface when the glass is lifted.) The visceral lining is attached to the outer surface of the lung; therefore, when the visceral lining is pulled outward, the lung is forced to expand. The natural tendency of the lung, however, is to recoil and collapse because of the elasticity of its tissue. This causes the lung to constantly pull inward as the thoracic cage is pulling it outward. This opposite pull creates a constant negative pressure, or a vacuum, in the pleural space (the space between the pleura).

After inhalation, the diaphragm and external intercostal muscles relax, allowing the chest wall to move inward and downward and, assisted by the inward pull of the elastic lung tissue, decrease the size of the thoracic cavity. As the size of the thorax decreases, the pressure inside increases to about 761 mmHg at sea level, which causes air to be forced out of the lungs. Because this process is brought about by the relaxation of muscles, with no energy expenditure, exhalation is considered a passive process.

Accessory Muscles

Use of accessory muscles (in addition to the diaphragm and intercostal muscles that are normally used for inhalation) may be required either to help increase the chest size to draw more air into the chest and lungs, or to help decrease the chest size to force air out of the lungs and chest. (The accessory muscles of inhalation are listed in Table 8-2.) Contracting the accessory muscles uses more energy than normal. Keep in mind that adequate amounts of oxygen must be constantly delivered to the cells to produce energy. A patient who needs to use accessory muscles to inhale may already be experiencing a lack of oxygen delivery and energy production. If the patient lacks the energy needed to contract both regular and accessory muscles of inhalation, the respiratory muscles will begin to fail. This will result in inadequate ventilation, which will compound the patient’s problems with a further decrease in oxygen delivery to cells.

Accessory Muscles of Exhalation. Exhalation is normally a passive process, requiring no expenditure of energy. However, if the patient is struggling to expel air from the lungs, the accessory muscles of exhalation may be used to create more positive pressure in the chest. (The accessory muscles of exhalation are listed in Table 8-2.) If the accessory muscles are used, exhalation becomes an active process, requiring energy. If the patient is also using accessory muscles and additional energy to inhale, the extra energy needed for exhalation may cause the respiratory muscles to fatigue, leading to respiratory failure.

A bellows is a device that pushes air out through a narrow opening when its sides are squeezed together and draws air in when its sides are pulled apart. The movement of air during ventilation relies on what is often called a bellows action of the chest. An injury or illness that interferes with that bellows action will impede the ability of the chest to create the pressure changes necessary to draw air into the lungs and force air out of the lungs. An injury that keeps the chest from expanding properly, such as compression, multiple rib fractures, or severe chest wall injury, will lead to a reduced creation of negative pressure inside the chest, reduced air volume drawn in to the lungs, and less oxygen made available for gas exchange. This will eventually lead to cellular hypoxia.

Compliance and Airway Resistance

Two conditions that may require the use of accessory muscles to generate a greater force to fill and empty the lungs are higher airway resistance and poor compliance. Compliance is a measure of the ability of the chest wall and lungs to stretch, distend, and expand. A condition that would cause the lungs or chest wall to become stiff would decrease compliance. A decrease in compliance would make it more difficult for the patient to move air in and out of the lungs. This also would make it more difficult for you to ventilate the patient artificially. Conditions such as pneumonia and pulmonary edema (discussed in Chapter 16, “Respiratory Emergencies”) decrease compliance within the lungs. Structural problems with the chest wall can also lead to poor compliance, for example a flail segment where two or more ribs are fractured in more than one place (discussed in detail in Chapter 34, “Chest Trauma”) or neuromuscular diseases affecting the ability of the chest muscles to contract.

Airway resistance is related to the ease of airflow down the conduit of airway structures leading to the alveoli. A higher airway resistance makes it more difficult

to move air through the conducting airways; a lower airway resistance makes it easier to move air. Higher airway resistance requires the patient to work harder to breathe, expending more energy and possibly using accessory muscles, which may accelerate respiratory muscle fatigue and failure. The most common cause of increased airway resistance is edema (swelling) within the airway structure. Mucus and constriction of the bronchioles will also decrease the radius of the airway and increase resistance.

Poor compliance and higher airway resistance may lead to less air available in the alveoli for gas exchange. This will result in less oxygen in the blood that is delivered to the cells, potentially resulting in cellular hypoxia.

**Minute Ventilation**

Minute ventilation, also known as minute volume, is the amount of air moved in and out of the lungs in one minute. It is determined by multiplying the tidal volume by the frequency of ventilation in one minute. The tidal volume ($V_t$) is the volume of air breathed in with each individual breath. The frequency of ventilation ($f$) is generally calculated as the number of ventilations in one minute. The formula is:

$$
\text{Minute ventilation} = \text{tidal volume} \times \text{frequency of ventilation (f/minute)}
$$

An average-sized adult has a tidal volume of approximately 500 mL and breathes approximately 12 times per minute at rest. Thus, the minute ventilation for an average-sized adult would be calculated as:

$$
\text{Minute ventilation} = 500 \text{ mL} \times 12/\text{minute}
$$

An average-sized adult moves approximately 6,000 mL of air in and out of the lungs in one minute. You will not be expected to measure or calculate the minute ventilation in the prehospital environment. The importance of understanding the calculation of minute ventilation is summarized in the following points:

- A decrease in tidal volume will decrease the minute ventilation.
- A decrease in frequency of ventilation will decrease the minute ventilation.
- A decrease in minute ventilation will reduce the amount of air available for gas exchange in the alveoli.
- A decrease in minute ventilation can lead to cellular hypoxia.
- To ensure adequate ventilation, the patient must have both an adequate tidal volume and an adequate rate of ventilation.

A patient may increase his frequency of ventilation to compensate for a decrease in tidal volume in order to maintain an adequate minute ventilation. As an example, an average-sized person is hypoventilating as a result of a low tidal volume of only 200 mL. If the patient maintains a ventilatory rate of 12/minute, the minute ventilation would be:

$$
\text{Minute ventilation} = 200 \text{ mL} \times 12/\text{minute}
$$

**Minute ventilation = 2,400 mL or 2.4 L/minute**

A minute ventilation of 2,400 mL or 2.4 liters/minute for this average-sized adult is 3,600 mL (6,000 mL – 2,400 mL = 3,600 mL) or 3.6 liters/minute less than normal, resulting in a significantly decreased amount of air moved during one minute of ventilation. This would most likely lead to a reduced amount of air in the alveoli, decreased gas exchange, and cellular hypoxia.

One way to compensate for a decreased minute ventilation is to increase the ventilatory rate. If the patient just described increases his ventilatory rate to 28 breaths/minute, the minute ventilation would be:

$$
\text{Minute ventilation} = 200 \text{ mL} \times 28/\text{minute}
$$

**Minute ventilation = 5,600 mL or 5.6 L/minute**
With a tidal volume of 200 mL and a ventilatory rate of 28/minute, it appears as if the minute ventilation is near the normal of 6,000 mL or 6 liters/minute. However, even though the minute ventilation appears to be near normal in this patient example, severe hypoxia may still occur as a result of a small amount of air actually getting to the alveoli for gas exchange. Increasing the frequency of ventilation may improve the amount of air moved in and out of the respiratory tract in one minute; however, if the tidal volume is too low, an adequate amount of air may never make it completely down to the alveoli for gas exchange but will instead remain in the trachea and major bronchi.

**Alveolar Ventilation**

Alveolar ventilation is the amount of air moved in and out of the alveoli in one minute. The key in this definition is specifically the amount of air moving in and out of the alveoli—unlike minute ventilation where the calculation is concerned only with air movement in and out of the respiratory tract and lungs.

Alveolar ventilation is related to the concept of anatomical dead air space. Dead air space \( (V_D) \) consists of anatomical areas in the respiratory tract where air collects during inhalation—areas where, however, no gas exchange occurs. Thus, the air that moves in and out of these areas is not involved in gas exchange and is wasted. In the average-sized adult, approximately 150 mL of the tidal volume is lost in the dead air space. Thus, of the 500 mL of air breathed in, only 350 mL reaches the alveoli for gas exchange. The equation is:

\[
\text{Alveolar ventilation} = (\text{tidal volume} - \text{dead air space}) \times \text{frequency of ventilation/minute}
\]

\[
\text{Alveolar ventilation} = (V_T - V_D) \times f/\text{minute}
\]

The alveolar ventilation for an average-sized adult with a tidal volume of 500 mL breathing at a rate of 12/minute would be calculated as follows:

\[
\text{Alveolar ventilation} = (500 \text{ mL} - 150 \text{ mL}) \times 12/\text{minute}
\]

\[
\text{Alveolar ventilation} = 4,200 \text{ mL} \text{ or } 4.2 \text{ L/minute}
\]

This calculation reveals that of the 6,000 mL or 6 liters/minute breathed in and out (minute ventilation), only 4,200 mL or 4.2 liters/minute reach the alveoli for gas exchange. Approximately 1,800 mL or 1.8 liters/minute of air fills the dead air space and is not used in gas exchange. This explains why exhaled air contains an oxygen concentration of 17 to 18 percent when the person is breathing in 21 percent oxygen. The oxygen in air that reaches the alveoli passes into the bloodstream and is replaced with waste carbon dioxide that passes from the blood into the alveoli. The question, therefore, is why there is any oxygen at all in exhaled air. The answer is that the air initially exhaled was not involved in gas exchanges because it was housed in the dead air spaces and still contains the higher concentrations of oxygen. This also explains how mouth-to-mouth ventilation provides an adequate amount of oxygen from the exhalation of the person providing the ventilation.

With alveolar ventilation, just as was true with minute ventilation, tidal volume and frequency of ventilation affect the amount of air from each ventilation that ends up in the alveoli. A reduction in tidal volume may dramatically reduce the alveolar ventilation, even when the patient increases the frequency of ventilation in order to compensate. Using the earlier example, it was found that if the patient began to hypoventilate with a tidal volume of 200 mL per breath but increased his rate of ventilation to 28/minute, his minute ventilation was near normal; however, he was very prone to hypoxia. Consider his alveolar ventilation in the following equation:

\[
\text{Alveolar ventilation} = (200 \text{ mL} - 150 \text{ mL}) \times 28/\text{minute}
\]

\[
\text{Alveolar ventilation} = 1,400 \text{ mL} \text{ or } 1.4 \text{ L/minute}
\]

Recall that his average normal alveolar ventilation was 4,200 mL or 4.2 liters/minute. Although he more than doubled his ventilatory rate, he is only getting 1,400 mL or 1.4 liters/minute of air into his alveoli for gas exchange. This occurs because the dead air space fills first, regardless of the volume breathed in with each ventilation. This leaves very little volume of air to reach the alveoli where gas exchange occurs, causing a dramatic reduction in the amount of oxygen in the blood and resulting in cellular hypoxia. This patient requires positive pressure ventilation so that more air can be forced into his alveoli to improve gas exchange. If you were to put this patient on supplemental oxygen only, you would not increase the amount of air getting into the alveoli. The air in the dead air space would be enriched with oxygen, but it might be exhaled from the lungs without ever reaching the alveoli.

The key points to consider with alveolar ventilation are:

- The patient may begin to breathe faster to move more air in and out of the thorax; however, that does not mean he is getting more oxygen into his alveoli for gas exchange.
- The dead air spaces will fill first regardless of the volume of air breathed in and the amount available to the alveoli.
- To improve gas exchange in the patient with an inadequate tidal volume, you must provide positive pressure ventilation to move more air into the alveoli.
- By simply placing a patient with an inadequate tidal volume on oxygen, you will not improve ventilation or reverse the cellular hypoxia.
- Assessing the tidal volume is as important as assessing the ventilatory rate.
Breathing is mostly an involuntary process that is controlled by the autonomic nervous system to maintain normal gas exchange. Receptors within the body constantly measure the amount of oxygen ($O_2$), carbon dioxide ($CO_2$), and hydrogen ions (pH) and send signals to the brain to adjust the rate and depth of respiration (Figure 8-6 ■). You do have some voluntary control over your breathing that allows you to hold your breath and alter your breathing pattern during talking, laughing, and singing. Primary involuntary control is through the respiratory center located in the brainstem, which sends out stimulatory impulses to the respiratory muscles.

**Chemoreceptors**

Chemoreceptors are specialized receptors that monitor the pH, carbon dioxide, and oxygen levels in arterial blood. There are two groups of chemoreceptors: central and peripheral.
Central Chemoreceptors. The central chemoreceptors are located near the respiratory center in the medulla. These receptors are most sensitive to carbon dioxide and changes in the pH of the cerebrospinal fluid (CSF). The pH is a measurement of hydrogen ion concentration. (The abbreviation pH stands for “potential of hydrogen.”) The pH in CSF is a direct reflection of the carbon dioxide level of the arterial blood. The carbon dioxide is able to cross over the blood-brain barrier and into the CSF. Once it is in the CSF, it combines with water (H₂O) to form carbonic acid. Thus, you can consider the following association between CO₂ and acid:

The greater the amount of CO₂ in the blood, the greater the amount of acid.
The lesser the amount of CO₂ in the blood, the lesser the amount of acid.

A molecule of carbonic acid consists of carbon, oxygen, and hydrogen atoms from the CO₂ and H₂O that combined to create the acid. The hydrogen ions dissociate from the carbonic acid and stimulate the central chemoreceptors. The central chemoreceptors are sensitive to small changes in the pH (hydrogen ion content) of CSF. Even small changes will stimulate a response in the rate and depth of breathing. Faster, deeper breathing blows off more CO₂ during exhalation. Slower, shallower breathing blows off less CO₂. The response of ventilation to stimulation by the central chemoreceptors from changes in CO₂ can be summarized as follows:

An increase in arterial CO₂ will increase the number of hydrogen ions in the CSF, stimulating an increase in the rate and depth of respiration to blow off more CO₂.
A decrease in arterial CO₂ will decrease the number of hydrogen ions in the CSF, causing a decrease in the rate and depth of respiration to blow off less CO₂.

Peripheral Chemoreceptors. The peripheral chemoreceptors are located in the aortic arch and the carotid bodies in the neck. These chemoreceptors are also somewhat sensitive to CO₂ and pH but are most sensitive to the level of oxygen in the arterial blood. As the level of oxygen in the blood decreases, the peripheral chemoreceptors signal the respiratory center in the brainstem to increase the rate and depth of respiration. It takes a significant decrease in the arterial oxygen content to trigger the peripheral chemoreceptors to stimulate the respiratory center. The activity of the peripheral chemoreceptors can be summarized this way:

A significant decrease in the arterial oxygen content will cause an increase in the rate and depth of respiration to increase the content of oxygen in the blood.

Stimulation by the central chemoreceptors and the peripheral chemoreceptors together has a greater influence on the rate and depth of ventilation than stimulation from either one by itself.

Hypoxic Drive. Normally, a person’s rate and depth of breathing are regulated primarily by the amount of carbon dioxide in the blood. This is referred to as a hypcapnic or hypercarbic drive.

The situation is different for patients with chronic obstructive pulmonary disease (COPD), such as emphysema. These patients have a tendency to retain carbon dioxide in arterial blood as a result of their poor gas exchange. When the arterial CO₂ level is chronically elevated, the central chemoreceptors become insensitive to the small changes that typically stimulate ventilation. The peripheral chemoreceptors then become the primary stimulus for ventilation; instead of a small increase in carbon dioxide level being a strong stimulus for ventilation, the peripheral chemoreceptors rely on a decrease in the oxygen level to stimulate ventilation. Hypoxia becomes the stimulus for ventilation in place of hypercarbia. This is known as hypoxic drive.

Lung Receptors

There are three types of receptors within the lungs that provide impulses to regulate respiration. These are irritant receptors, stretch receptors, and J-receptors.

Irritant Receptors. Irritant receptors are found in the airways and are sensitive to irritating gases, aerosols, and particles. Irritant receptors will stimulate a cough, bronchoconstriction, and an increased ventilatory rate.

Stretch Receptors. Stretch receptors are found in the smooth muscle of the airways and measure the size and volume of the lungs. These receptors stimulate a decrease in the rate and volume of ventilation when stretched by high tidal volumes to protect against lung overinflation.

J-Receptors. J-receptors are found in the capillaries surrounding the alveoli and are sensitive to increases in pressure in the capillary. When activated, the J-receptors stimulate rapid, shallow ventilation.

Respiratory Centers in the Brainstem

With regard to control of breathing, there is much that is still unknown. It is generally accepted that there are three respiratory control centers in the brainstem: the dorsal respiratory group, the ventral respiratory group, and the pontine respiratory center. The ventral respiratory group and dorsal respiratory group are located in the medulla oblongata in an area referred to as the medullary respiratory center. The pontine respiratory center, also referred to as the pneumotaxic center, is located in the pons of the brainstem. These centers receive sensory input and transmit impulses to the skeletal muscles controlling ventilation, causing them to either contract or relax, depending on the impulse.

The ventral respiratory group (VRG) is a column of neurons located in the anterior portion of the medulla. The VRG contains both inspiratory and expiratory neurons that are responsible for initiating neural
impulses that stimulate the external intercostal muscles and the diaphragm, causing them to contract, which results in inhalation.

It was once thought that the dorsal respiratory group (DRG) was responsible for the primary control of inhalation and exhalation; however, researchers have recently discovered that the ventral respiratory group is responsible for initiating the basic rhythm of respiration. The DRG, located posterior to the VRG, relays its sensory information to the VRG to provide further input on depth and rate of respiration. However, the VRG is solely responsible for sending the nerve impulses to the spinal cord to be transmitted to the diaphragm and external intercostal muscles causing them to contract.

The VRG and DRG function in every respiratory cycle, whether during quiet breathing or during forced breathing with the accessory muscles involved. In a typical respiratory cycle, the VRG inspiratory (VRGI) neurons stimulate the external intercostal muscles and diaphragm for two seconds, resulting in inhalation. Then the VRG expiratory (VRGE) neurons, along with the pontine respiratory group, inhibit the inspiratory (VRGI) neurons, causing the nervous impulse transmission to the diaphragm and external intercostal muscles to cease for a total of 3 seconds. With the VRGI shut off, the external intercostal muscles and diaphragm relax, causing exhalation to occur. After the 3 seconds of exhalation, the VRGI becomes active again, sending impulses to the respiratory muscles that cause inhalation to begin again. During the entire cycle, the DRG is sending input to the VRG in regard to depth and rate of respiration. The process continues to repeat itself. The 2-second on and 3-second off rhythm produces an average respiratory rate of 12 per minute in the adult patient.

In forced inhalation, the VRG, with input from the DRG, stimulates the external intercostal muscles and diaphragm to contract to their maximal level, and the VRGI stimulates the accessory muscles to contract to further increase the size of the thorax and the inspiratory effort. At the end of inhalation, the VRGI stops sending impulses to the muscles. The respiratory muscles relax and exhalation occurs.

In forced exhalation, the VRGE becomes active and stimulates contraction of the internal intercostal muscles and the abdominal muscles, decreasing thorax size, increasing the positive pressure inside the chest, and forcing exhalation. Stimulation by the VRGI causes muscular contraction; therefore, exhalation becomes an active process under its control.

The pontine respiratory center, also known as the pneumotaxic center, sends inhibitory impulses to the VRGI to turn off the inhalation. These inhibitory impulses from the pontine respiratory center work in conjunction with the inhibitory impulses generated by the VRGE neurons to promote a smooth transition between inhalation and exhalation.

A disturbance to the respiratory centers in the brainstem from injury or illness may alter the pattern and depth of ventilation. This may produce inadequate ventilation and abnormal ventilatory patterns that may impede adequate gas exchange and promote cellular hypoxia, requiring ventilatory support.

**Ventilation/Perfusion Ratio**

The ventilation/perfusion (V/Q) ratio describes the dynamic relationship between the amount of ventilation the alveoli receive and the amount of perfusion through the capillaries surrounding the alveoli. This relationship determines the quality of gas exchange across the alveolar-capillary membrane, which influences the amount of oxygen entering the blood and the amount of carbon dioxide exiting the blood. The dynamic relationship between ventilation and perfusion in the lungs can be used to explain the etiology (causes) of hypoxemia, or inadequate oxygen concentrations in the blood (Figure 8-7).

In the ideal lung, each alveolus would receive an adequate amount of ventilation and a matching amount of blood flow through the surrounding capillary, resulting in a V/Q ratio that is equal. This ideal condition never exists because of the effects of gravity on blood flow, the structure of the lungs, and shunting of blood.

With an individual in a standing position, gravity pulls the lungs downward toward the diaphragm, compressing the lower lobes. As the lower lobes are compressed and blood is pulled down to the bases of the lungs, air travels upward to the apexes (tops) of the lungs and increases the residual volume. Interestingly, the alveoli in the apexes of the lungs have a greater residual volume of air, are larger, and have a higher surface tension, but they are fewer in number as compared to other areas of the lungs. These larger alveoli in the apexes have a higher surface tension, which makes them less compliant and harder to inflate during ventilation. Thus, the tidal volume is shifted to the lower lobes where the lung is more compliant and there is less surface tension. Because gravity pulls the blood downward, less pressure is required to perfuse the lower lobes of the lungs as compared to the apexes. As a result, the bases of the lungs receive a greater amount of blood and are much better perfused than the apexes. This is a desirable condition, since the greatest amount of ventilation also exists in the base of the lungs.

The ventilation/perfusion ratio is never at an ideal state in any zones of the lungs. In the apexes, the amount of available ventilation in the alveoli exceeds the amount of perfusion through the pulmonary capillaries; that is, there is more oxygen available in the alveoli than the supply of blood is able to pick up and transport. This is considered to be wasted ventilation. In the bases, the amount of perfusion exceeds the amount of ventilation; this means there is more blood moving through the pulmonary capillaries than there is alveolar oxygen available for it to pick up. This is considered to
be wasted perfusion. Overall, under normal conditions, perfusion exceeds the amount of available ventilation.

**Pressure Imbalances**

The perfusion of blood through the pulmonary capillaries is affected by the amount of air and pressure inside the alveoli and the pressure of the blood flowing through the capillary bed (Figure 8-8). If the pressure in an alveolus exceeds the blood pressure in the capillary bed, blood flow through the capillary stops. This is most likely to occur in the apexes of the lungs where the pressure inside the alveoli is highest and the blood flow is lowest. However, it may also occur in the patient who is losing blood from an injury and has a decreasing blood pressure. A decrease in the systemic blood pressure will cause the pressure in the pulmonary capillaries to also decrease. If the patient does not have a chest or lung injury, the lungs will continue to receive adequate volumes of air, creating adequate pressure in
the alveoli. However, the reduction in blood pressure may allow the alveolar pressure to exceed the pulmonary capillary pressure and impede blood flow. This will result in poor pulmonary perfusion, hypoxemia (reduced oxygen concentrations in the blood), and cellular hypoxia (oxygen deficiency in the cells).

Ventilatory Disturbances
A disturbance on the ventilation side of the ventilation/perfusion ratio can lead to hypoxia (Figure 8-9 ■). If a condition or injury causes less oxygenated air to be available in the alveoli for the amount of blood flowing through the pulmonary capillaries, the end result will be less oxygen saturating the blood and less oxygen delivered to the cells, creating hypoxemia and cellular hypoxia. As an example, if a patient is having an asthma attack and the bronchioles are inflamed and constricted, the restricted airways reduce airflow and provide less oxygenated air to the alveoli for gas exchange. The blood pressure is not affected; therefore, the amount of blood passing through the pulmonary capillaries remains normal. A ventilation disturbance has been created by making less oxygen available to the blood passing through the capillaries. In this condition, there is wasted perfusion, since the blood is available but there is an inadequate amount of oxygen to be picked up. This disturbance in ventilation leads to hypoxemia and cellular hypoxia.

In the situation just described in which an asthma attack has caused a ventilatory disturbance, you must improve the ventilation side of the ventilation/perfusion ratio by relieving the bronchiolar airway restriction and increasing the amount of oxygenated air entering the alveoli. An EMT would achieve this by placing the patient on oxygen and administering a medication to dilate the bronchioles to improve airflow. This treatment would not only increase the amount of air in the alveoli, it would also increase the concentration of oxygen in the alveolar air, making more oxygen available for the blood moving through the pulmonary capillaries. This would reduce or eliminate the hypoxemia and cellular hypoxia.

Perfusion Disturbances
A perfusion disturbance may also lead to severe cellular hypoxia (review Figure 8-9 ■). Consider a patient you encounter who has cut his radial artery on a saw and suffered severe blood loss. The patient has no chest or lung injury and has an increased rate and depth of ventilation. His minute ventilation and alveolar ventilation are increased; however, his cells are becoming hypoxic. Although he is moving more oxygenated air into the alveoli, his blood loss has significantly reduced the amount of blood flow through the pulmonary capillaries. This represents a perfusion disturbance, because there is not enough blood to pick up the oxygen available in the alveoli. This would create a state of wasted ventilation, hypoxemia, and cellular hypoxia. By placing the patient on oxygen, you might reduce some of the cellular hypoxia; however, it will not be eliminated until the perfusion disturbance is fixed. The bleeding must be stopped, and this patient needs to receive fluid and blood to increase the flow and pressure in the pulmonary capillaries so there is enough hemoglobin available for oxygen in the alveoli to attach to and be transported to the cells.

Hypoxia generally results from a ventilation or perfusion disturbance. A myriad of conditions can cause one of these disturbances to occur. The management of hypoxia resulting from a ventilatory disturbance should focus on improving ventilation and oxygenation. Managing a disturbance in perfusion must focus on increasing blood flow through the pulmonary capillaries, the availability of hemoglobin, and delivery of oxygen to the cells.

Transport of Oxygen and Carbon Dioxide by the Blood
Oxygen must be continuously delivered by the blood to the cells in order for normal cellular metabolism to occur. Carbon dioxide, a by-product of aerobic metabolism, must be carried back to the lungs to be blown off in exhalation. A disturbance in the transport system may lead both to cellular hypoxia, a lack of oxygen available to the cells, and to hypercarbia, a buildup of carbon dioxide in the blood. Both hypoxia and hypercarbia pose problems for normal cellular function and stability.

Both oxygen and carbon dioxide are transported by the blood, but in different ways (Figure 8-10 ■). It is important to remember that oxygen and carbon dioxide move from areas of higher concentration to areas of lower concentration. This helps explain the movement of gas molecules between alveoli and capillaries and between capillaries and cells.
As carbon dioxide leaves the cells, it crosses over into the capillaries where a small amount dissolves into the plasma. A larger amount of CO₂ attaches to hemoglobin. The largest amount of CO₂ diffuses into the red blood cell and combines with water to form carbonic acid, which then dissociates into hydrogen and bicarbonate. The bicarbonate exits the cell and is transported in the blood plasma. When the blood reaches the pulmonary circulation, the bicarbonate diffuses back into the red blood cell where it combines with hydrogen and splits back into water and carbon dioxide. Regardless of the transport mechanism, the carbon dioxide diffuses into the alveoli and is released through exhalation.

### Alveolar/Capillary Gas Exchange

After inhalation, the alveoli are filled with oxygen-rich air that contains very little carbon dioxide. Conversely, the venous blood that flows through the capillaries surrounding the alveoli contains low levels of oxygen and higher amounts of carbon dioxide. Since gas molecules naturally move from an area of high concentration to an area of low concentration, the high oxygen content in the alveoli moves across the membranes and into the capillaries where the oxygen content is very low. (Review Figure 8-7, top inset.) There, as described earlier, a small amount of oxygen dissolves in the plasma and a larger amount attaches to the hemoglobin. Simultaneously, carbon dioxide moves in the opposite direction, from the high levels contained in the capillaries into the alveoli where the CO₂ content is low. It happens this way: The bicarbonate ions in the blood convert to water and CO₂. Additional CO₂ diffuses out of the plasma and from the hemoglobin. All of this CO₂ crosses from the capillaries into the alveoli.

After these exchanges—from alveoli to capillaries and from capillaries to alveoli—the alveoli contain low

---

**Figure 8-10** Oxygen is transported in the blood two ways: attached to hemoglobin and dissolved in plasma. Carbon dioxide is transported in the blood three ways: as bicarbonate, attached to hemoglobin, and dissolved in plasma.
levels of oxygen and high levels of carbon dioxide, while the blood in the capillaries contains high levels of oxygen and low levels of carbon dioxide. Basically, the gases have switched concentrations. The carbon-dioxide-rich air in the alveoli is exhaled from the lungs. The oxygen-rich blood in the capillaries is transported from the pulmonary circulation to the left atrium and then to the left ventricle of the heart, from which it is ejected into the aorta and to the arteries throughout the body. This blood that is circulating throughout the body will be used in the cell/capillary gas exchange described next.

**Cell/Capillary Gas Exchange**

The blood that was ejected from the left ventricle into the arteries contains high concentrations of oxygen and low concentrations of carbon dioxide. This blood travels through an artery and then enters a smaller arteriole that leads to a capillary bed that is surrounded by cells. During cell metabolism, the cells have used oxygen and produced carbon dioxide as a by-product. Thus, while the capillary beds contain blood that is high in oxygen and low in carbon dioxide, the cells contain low levels of oxygen and high levels of carbon dioxide.

As the blood enters the capillary, oxygen breaks free of the hemoglobin and diffuses out of the plasma, crosses the capillary membrane, and enters the cell. Simultaneously, carbon dioxide leaves the cell and crosses over into the capillary where it dissolves in the plasma, attaches to hemoglobin, or enters the red blood cell to be converted to bicarbonate. (Review Figure 8-7, bottom inset.) As the blood leaves the capillary, it enters a small venule from which it is eventually dumped into a larger vein. The blood in the venules and veins contains low concentrations of oxygen and high concentrations of carbon dioxide. This carbon-dioxide-carrying blood is transported to the right atrium of the heart, from which it enters the right ventricle and is pumped to the lungs. There the blood enters the pulmonary capillaries to give off carbon dioxide and pick up oxygen in the alveolar/capillary gas exchange that was previously described.

For the cells to receive an adequate amount of oxygen and eliminate carbon dioxide, both the alveolar/capillary gas exchange and cell/capillary gas exchange must be functioning properly. A disturbance in either will result in inadequate amounts of oxygen being delivered to the cells or will result in the accumulation of carbon dioxide.

**Blood Volume**

One of the determinants of an adequate blood pressure and perfusion is blood volume. An adult has approximately 70 mL of blood for every kilogram (2.2 lb) of body weight. Thus, a patient who weighs 154 lb or 70 kg would have approximately 4,900 mL or 4.9 liters of blood volume. Blood volume correlates with body mass; therefore, a larger patient would normally have a greater blood volume. The loss of 1 liter of blood in a 100-lb patient would be much more significant than in a 200-lb patient.

**Composition of Blood**

Blood is composed of formed elements and plasma. The formed elements, which are cells and proteins, make up approximately 45 percent of blood composition. Plasma is the fluid component that accounts for the remaining 55 percent. The primary function of plasma is to suspend and carry the formed elements. Plasma is made up primarily of water and plasma proteins. Water comprises 91 percent of plasma. The plasma proteins consist of albumin, antibodies, and clotting factors. Albumin is a large molecule that does not pass easily through a capillary; it plays a major role in maintaining the fluid balance in the blood, as will be explained later in the section on plasma oncotic pressure. Antibodies are produced by the lymphatic system and are responsible for the defense against infectious organisms. The clotting factors are key in coagulation of blood from damaged vessels. Fibrinogen is the most plentiful clotting factor and is the precursor to the fibrin clot.

The formed elements in the blood are red blood cells, white blood cells, and platelets. Red blood cells (erythrocytes) make up approximately 48 percent of the blood cell volume in men and 42 percent in women. The red blood cells, which contain hemoglobin, are primarily responsible for carrying oxygen and delivering it to cells for metabolism. The white blood cells (leukocytes) protect the body against infection and eliminate dead and injured cells and other debris. The platelets (thrombocytes) are not actual cells but fragments that play a major role in blood clotting and the control of bleeding.

**Distribution of Blood**

Blood is distributed throughout the cardiovascular system (Table 8-3). The majority of blood is housed within the venous system, which is also known as a reservoir or capacitance system. The venous system is capable
of enlarging or reducing its capacity to respond to increases or decreases in the blood volume. As a patient bleeds, the venous volume is continuously reduced regardless of whether the bleeding is from a vein, an artery, or a capillary.

The venous system is responsible for supplying the right side of the heart with an adequate volume of blood. If the volume entering the right side of the heart is decreased, the amount ejected from the left ventricle, through the arteries, and to the cells, is also reduced. Thus, the venous volume plays a major role in maintaining blood pressure and adequate perfusion of the cells. This will be discussed in more detail later in the chapter. The capillary network is the site of gas exchange occurring with the alveoli or cells.

### Hydrostatic Pressure

**Hydrostatic pressure** is the force inside the vessel or capillary bed generated by the contraction of the heart and the blood pressure. Hydrostatic pressure exerts a “push” inside the vessel or capillary. That is, it wants to push fluid out of the vessel or capillary, through the vessel wall, and into the interstitial space. A high hydrostatic pressure would force more fluid out of the vessel or capillary and promote edema—swelling from excess fluid outside the vessels (Figure 8-11).

As an example, if a patient has a left ventricle that is failing and unable to pump blood effectively, the volume and pressure in the left atrium, pulmonary vein, and pulmonary capillaries rise. This occurs because the pulmonary capillaries, pulmonary vein, and left atrium are the pathways by which blood enters the left ventricle. When the left ventricle fails to empty effectively, blood backs up into the left atrium and pulmonary vessels, which increases the pressure within them. The increased hydrostatic pressure inside the pulmonary capillaries forces fluid out of them. The extruded fluid has a tendency to collect in the spaces between the alveoli and capillaries and around the alveoli, which reduces the ability of oxygen and carbon dioxide to be exchanged across the alveolar/capillary membrane. This disturbance reduces the blood oxygen content, leading to cellular hypoxia, and also causes the blood to retain carbon dioxide. The fluid will eventually begin to collapse and fill the alveoli, further diminishing gas exchange. This condition is known as pulmonary edema.

#### Plasma Oncotic Pressure

**Plasma oncotic pressure**, also known as colloid oncotic pressure or oncotnic pressure, is responsible for keeping fluid inside the vessels. A force is generated inside vessels by large plasma proteins, especially albumin, that attract water and other fluids. Opposite to hydrostatic pressure, oncotic pressure exerts a “pull” inside the vessel. A high oncotic pressure would pull fluid from outside the vessel, through the vessel wall, and into the vessel. (Review Figure 8-11.)

A balance between hydrostatic pressure and plasma oncotic pressure must be maintained for equilibrium of fluid balance. The effects of high and low hydrostatic and oncotic pressures are summarized as follows:

- A high hydrostatic pressure will push fluid out of a capillary and promote edema.
- A low hydrostatic pressure will push less fluid out of the vessel.
- A high oncotic pressure will draw excessive amounts of fluid into the vessel or capillary and promote blood volume overload.
- A low oncotic pressure will not exert an adequate pull effect to counteract the push of hydrostatic pressure and will therefore promote loss of vascular volume and promote edema.

### Pump Function of the Myocardium

In order to have an adequate blood pressure and perfusion, the myocardium must work effectively as a pump. The heart is capable of varying its output to meet a wide range of physiological demands. It can drastically increase its pump function, up to sixfold. The pump function is typically expressed as the cardiac output. **Cardiac output** is defined as the amount of blood ejected by the left ventricle in 1 minute. The cardiac output has a major influence on blood pressure and perfusion, as will be discussed later in the chapter.

#### Cardiac Output

A normal cardiac output for an adult at rest is 5 liters/minute. That means the ventricles will pump the entire blood volume through the vascular system in 1 minute. If a drop of blood left the left ventricle, in 1 minute it...
should be back at the left ventricle. The cardiac output is determined by the heart rate and the stroke volume. Cardiac output is expressed by the following equation:

\[ \text{Cardiac output} = \text{heart rate} \times \text{stroke volume} \]

**Heart Rate**

The heart rate is defined as the number of times the heart contracts in 1 minute. The heart has the property of automaticity, meaning it can generate its own impulse. This is achieved through the conduction system with the sinoatrial (SA) node being the primary pacemaker. The heart rate can also be influenced to increase or decrease its rate of firing by several factors outside of the heart. The primary factors are hormones and the autonomic nervous system, composed of the sympathetic and parasympathetic systems. The influence of the autonomic nervous system on the heart rate is summarized as follows:

- An increase in stimulation by the sympathetic nervous system increases the heart rate.
- A decrease in stimulation by the sympathetic nervous system decreases the heart rate.
- An increase in stimulation by the parasympathetic nervous system decreases the heart rate.
- A decrease in stimulation by the parasympathetic nervous system increases the heart rate.

The sympathetic and parasympathetic nervous systems exert control over the heart rate through the cardiovascular control center located in the brainstem. The cardiovascular control center is composed of the cardioexcitatory center and the cardioinhibitory center. The cardioexcitatory center increases the heart rate by increasing sympathetic stimulation and decreasing parasympathetic stimulation. The cardioinhibitory center decreases the heart rate by decreasing sympathetic stimulation and increasing parasympathetic stimulation.

Direct neural stimulation provides an immediate response in the heart rate and force of ventricular contraction. In addition, stimulation of the sympathetic nervous system may cause the release of epinephrine and norepinephrine from the adrenal gland located on top of the kidney. The release of these hormones may take a few minutes; however, the response will be sustained as long as the hormones are continuously released and circulating. As discussed in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” the beta1 properties in the epinephrine will cause an increase in the heart rate and force of contraction.

**Stroke Volume**

**Stroke volume** is defined as the volume of blood ejected by the left ventricle with each contraction. Stroke volume is determined by preload, myocardial contractility, and afterload.

- **Preload** is the pressure generated in the left ventricle at the end of diastole (the resting phase of the cardiac cycle). Preload pressure is created by the blood volume in the left ventricle at the end of diastole. The available venous volume, which determines the volume of blood in the ventricle, consequently plays a major role in determining preload. An increase in preload generally increases stroke volume, which in turn increases the cardiac output (Figure 8-12a ■). Preload determines the force necessary to eject the blood out of the ventricle.

As blood fills the left ventricle, the muscle fibers stretch to house the blood. The stretch of the muscle fiber at the end of diastole determines the force available to eject the blood from the ventricle. This is known as the **Frank-Starling law of the heart.** As the blood volume increases in the left ventricle, the increased stretch in the muscle fibers generates a commensurate contraction force. In short, the volume of blood in the ventricle automatically generates a contraction forceful enough to eject it. There is a limit, however, to applicability of the
Frank-Starling law—a limit to the effectiveness of fiber stretch. In the case of a severely dilated ventricle where the fibers are overstretched, the heart will no longer be able to produce contractions strong enough to eject blood from the ventricle adequately.

In order to have an adequate stroke volume, the left ventricle must be able to generate enough force to effectively eject its blood volume. An increase in myocardial contractility will increase the stroke volume and improve cardiac output. Conversely, a decrease in myocardial contractility will lead to a decrease in stroke volume and a resulting decrease in cardiac output. For example, a patient with congestive heart failure will have a decrease in contractile force of the left ventricle that is likely to result in a diminished cardiac output. A patient who has suffered a heart attack will have a deadened portion of cardiac muscle that will no longer contribute to the contractile force. If the area of necrosis is large, the contractile force will be significantly reduced with a proportional decrease in stroke volume and cardiac output (Figure 8-12b).

**Afterload** is the resistance in the aorta that must be overcome by contraction of the left ventricle to eject the blood. The force generated by the left ventricle must overcome the pressure in the aorta to move the blood forward. A high afterload places an increased workload on the left ventricle. A chronically elevated diastolic blood pressure will create a high afterload, generating an increased myocardial workload that could lead to left ventricular failure over a period of time.

In general, a decrease in either the heart rate or stroke volume will decrease the cardiac output:

- A ↓ in heart rate = ↓ in cardiac output
- A ↓ in stroke volume = ↓ in cardiac output

The effects of heart rate, blood volume, myocardial contractility, autonomic nervous system stimulation, hormone release, and diastolic blood pressure on cardiac output are these:

- A decrease in heart rate will decrease cardiac output.
- An increase in heart rate, if not excessive, will increase cardiac output.
- A decrease in blood volume will decrease preload, stroke volume, and cardiac output.
- An increase in blood volume will increase preload, stroke volume, and cardiac output.
- A decrease in myocardial contractility will decrease stroke volume and cardiac output.
- An increase in myocardial contractility will increase stroke volume and cardiac output.
- Neural stimulation from the sympathetic nervous system will increase heart rate, myocardial contractility, and cardiac output.
- Neural stimulation from the parasympathetic nervous system will decrease heart rate, myocardial contractility, and cardiac output.
- Beta1 stimulation from epinephrine will increase heart rate, myocardial contractility, and cardiac output.
- Beta1 blockade (patient on beta blocker) will block beta1 stimulation, decrease heart rate, decrease myocardial contractility, and decrease cardiac output.
- An extremely high diastolic blood pressure will increase the pressure in the aorta, requiring a more forceful contraction to overcome the aortic pressure and a higher myocardial workload, and may weaken the heart and decrease the cardiac output over time.
- A reduction in the diastolic blood pressure will decrease the pressure in the aorta, require a less forceful contraction to overcome the aortic pressure, and reduce the myocardial workload, which may improve the cardiac output in a weakened heart.

A faster heart rate may increase cardiac output; however, if the rate is extremely fast the cardiac output may actually decrease. With excessively fast heart rates, usually >160 bpm in the adult patient, the time between beats is so short that there is not an adequate amount of time for the ventricles to fill. This reduces the preload, which in turn reduces the cardiac output.

### Systemic Vascular Resistance

**Systemic vascular resistance** is the resistance that is offered to blood flow through a vessel. As a vessel constricts (decreases its diameter), resistance inside the vessel increases, which typically increases pressure inside the vessel (Figure 8-13). Conversely, as a vessel dilates (increases its diameter), resistance inside the vessel decreases, which typically decreases pressure inside the vessel. **Vasoconstriction** is the term for a decrease in vessel diameter. **Vasodilation** is the term for an increase in vessel diameter. Vessel size influences blood pressure. Vasoconstriction decreases vessel size, increases resistance, and increases blood pressure. Vasodilation increases vessel diameter, decreases resistance, and decreases blood pressure.

Pressure within the vessels is greatest during cardiac contraction (systole) and least during cardiac relaxation (diastole). The basic measure of systemic vascular resistance changes from vasoconstriction and vasodilation.

**Figure 8-13** Systemic vascular resistance changes from vasoconstriction and vasodilation.
resistance is the diastolic blood pressure because it is assessed during the relaxation phase, indicating the resting pressure within the vessels. Systolic blood pressure, created by the wave of blood ejected from the left ventricle during contraction, increases the pressure within the vessels beyond their resting pressure.

An abnormally high diastolic blood pressure is not a desirable condition. The diastolic blood pressure is the pressure inside the arteries and the aortic root immediately prior to contraction of the left ventricle. The higher the diastolic blood pressure, the greater the resistance to blood being ejected from the left ventricle. That means the left ventricle has to work harder to pump the blood out against a higher diastolic pressure. If the diastolic blood pressure is chronically elevated, it will eventually cause the heart to fail. It is all related to resistance of flow and harder workloads.

As an example, a person is given two weights to lift simultaneously. The weight in the right hand weighs only 1 lb, whereas the weight in the left hand weighs 10 lb. Which extremity and muscle would become fatigued and fail first if the person were asked to continuously lift the weights? Obviously the left arm lifting the 10-lb weight would fatigue and fail first. Why? The muscle is working against a greater resistance. Relate this example to the heart of a patient with a chronically elevated diastolic blood pressure. The high resistance to blood flow causes the left ventricle to work harder to pump the blood out. If the left ventricle has to contract against the high resistance chronically, it eventually weakens and fails. This condition is known as left ventricular failure or congestive heart failure.

The autonomic nervous system influences the systemic vascular resistance. Direct neural stimulation from the sympathetic nervous system causes the vessels to constrict, increasing vessel resistance and pressure. Parasympathetic nervous system stimulation causes the vessels to dilate, reducing resistance and pressure. Additionally, epinephrine and norepinephrine are released by the adrenal gland in response to sympathetic stimulation have alpha properties. Alpha receptor stimulation causes the vessels to constrict, increasing the vessels’ resistance and pressure.

If the volume of blood inside a vessel decreases, one way to maintain the pressure is to decrease vessel size and increase resistance. When blood is being lost and overall volume is decreasing, vessels will usually compensate for this loss by continuing to contract to raise resistance and pressure. Blood pressure may thus be maintained at a normal level, making it appear as if no volume has been lost. That is why it is so important not only to evaluate the vital signs in a patient with blood loss but also to look for signs of poor perfusion.

Think back to the beginning of the chapter and the discussion of cellular metabolism. As vessels decrease in size to maintain blood pressure, they do so at the expense of cellular perfusion. As the vessels constrict, less blood flows through them and less oxygen is delivered to the cells. As oxygen delivery decreases, the cells change from aerobic to anaerobic metabolism.

The loss in energy is often noted in the patient’s general appearance at the scene. The patient with poor perfusion is typically quiet, reserved, and may actually appear sleepy. The patient who is screaming and yelling and constantly moving about has to have lots of energy in order to do so. There has to be an adequate delivery of oxygen and glucose to the cells to produce this amount of energy. Be careful not to mistake this high level of patient energy with the agitation and aggression experienced by patients whose brain cells are hypoxic.

The effects of the autonomic nervous system on the systemic vascular resistance are summarized as follows:

- Sympathetic stimulation causes vasoconstriction, which decreases vessel diameter and increases systemic vascular resistance.
- Parasympathetic stimulation causes vasodilation, which increases vessel diameter and decreases systemic vascular resistance.
- The alpha 1 properties in epinephrine and norepinephrine, released in response to sympathetic stimulation, cause vasoconstriction, which decreases vessel diameter and increases systemic vascular resistance.

### Systemic Vascular Resistance Effect on Pulse Pressure

The systolic blood pressure is a relative indicator of the cardiac output, whereas the diastolic blood pressure measures the systemic vascular resistance. If the systolic blood pressure is decreasing, it is an indication of a diminishing cardiac output. The following describes the effect of the systemic vascular resistance on diastolic blood pressure:

- An increase in the systemic vascular resistance will increase the diastolic blood pressure.
- A decrease in the systemic vascular resistance will decrease the diastolic blood pressure.

The pulse pressure is the difference between the systolic and the diastolic blood pressure readings. If the patient has a blood pressure of 132/74 mmHg, the pulse pressure would be derived by subtracting the diastolic from the systolic. In this case, the pulse pressure would be 58 mmHg (132 – 74 = 58). A narrow pulse pressure is defined as being less than 25 percent of the systolic blood pressure reading. In this case, a narrow pulse pressure would be less than 33 mmHg (132 x 25% = 33 mmHg).

In the patient with blood or fluid loss, a narrow pulse pressure is a significant sign. As a patient loses blood, the following occurs:

- **Blood loss ↓ → venous volume which ↓ → preload which ↓ → stroke volume which ↓ → cardiac output.**

The systolic blood pressure begins to decrease from the drop in cardiac output. One way the body attempts to compensate for the decrease in blood pressure is by...
Microcirculation

Microcirculation is the flow of blood through the smallest blood vessels—the arterioles, capillaries, and venules. As mentioned previously, the veins and venules primarily serve a capacitance function by pooling blood as needed and supplying it to the heart as necessary to maintain cardiac output. Arteries branch into arterioles, which are at the terminal ends of the arteries. The arterioles, which are made up of almost all smooth muscle, control the movement of blood into the capillaries. Vasodilation increases the capillary blood flow.

The true capillaries are the sites of exchange of nutrients, oxygen, carbon dioxide, glucose, waste products, and metabolic substances between the blood and the cells. Metarterioles are described often as thoroughfares or channels that connect the arterioles and venules. True capillaries branch from the metarterioles. Precapillary sphincters control the movement of blood through the true capillaries. If the precapillary sphincter is relaxed, blood moves through the capillary. If the precapillary sphincter is contracted, the blood is shunted away from the true capillary. The precapillary sphincters help to maintain arterial pressure and control the movement of blood through the capillary beds.

Three regulatory influences control blood flow through the capillaries: local factors, neural factors, and hormonal factors. Local factors are found in the immediate environment around or within the capillary structure, for example, temperature, hypoxia, acidosis, and histamine.
A cold temperature would cause the peripheral arterioles to constrict and precapillary sphincters to close, shunting blood away from the capillaries in an attempt to reduce the blood exposure to the cold environment. The opposite would be true in a warm environment where the arterioles would dilate and the precapillary sphincters would open to shunt the blood to the periphery where it can cool.

Neural factors are associated with the influence of the sympathetic and parasympathetic nervous systems on the arterioles and precapillary sphincters. Sympathetic nervous stimulation would cause the arterioles to constrict and precapillary sphincters to close. Parasympathetic stimulation would cause the arterioles to dilate and the precapillary sphincters to open.

Hormones may also control the movement of blood through the capillaries. As an example, the alpha\textsubscript{1} stimulation from epinephrine causes the arterioles to constrict and the precapillary sphincters to close.

In a resting state, the local factors predominantly control blood flow through the capillaries. When adaptation is necessary, the neural factors will change the capillary blood flow. Hormones are usually responsible for a sustained effect on the arterioles and capillaries.

**Blood Pressure**

As previously noted, the systolic blood pressure is a measure of cardiac output. The diastolic blood pressure is a measure of systemic vascular resistance. The body’s compensation mechanisms are geared toward maintaining pressure inside the vessel and perfusion of the cells.

The blood pressure is derived by multiplying two major factors: cardiac output and systemic vascular resistance:

\[
\text{Blood pressure (BP)} = \text{cardiac output (CO)} \times \text{systemic vascular resistance (SVR)}
\]

Both the cardiac output and systemic vascular resistance have a direct effect on the blood pressure, which is summarized as follows:

- An increase in cardiac output will increase the blood pressure.
- A decrease in cardiac output will decrease the blood pressure.
- An increase in the heart rate will increase the cardiac output which will increase the blood pressure.
- A decrease in the heart rate will decrease the cardiac output which will decrease the blood pressure.
- An increase in the stroke volume will increase the cardiac output which will increase the blood pressure.
- A decrease in the stroke volume will decrease the cardiac output which will decrease the blood pressure.
- An increase in systemic vascular resistance will increase the blood pressure.
- A decrease in systemic vascular resistance will decrease the blood pressure.

Perfusion of cells is linked to the blood pressure. In order to maintain adequate perfusion, the blood must be pushed with enough force to constantly deliver oxygen and glucose to the cells and remove carbon dioxide and other waste products. The general effect of blood pressure on perfusion is:

- An increase in blood pressure will increase cellular perfusion.
- A decrease in blood pressure will decrease cellular perfusion.

**Regulation of Blood Pressure by Baroreceptors and Chemoreceptors**

The blood pressure is monitored and regulated by both baroreceptors and chemoreceptors.

**Baroreceptors.** Baroreceptors are stretch-sensitive receptors, located in the aortic arch and carotid sinuses, that detect changes in blood pressure (Figure 8-15). As the pressure inside the vessels changes, it decreases or increases the stretch of the fibers of the baroreceptors. The baroreceptors, having thus detected the change in blood pressure, send impulses to the cardio regulatory and vasomotor centers in the brainstem to make compensatory alterations in the blood pressure. The cardio regulatory center consists of the cardioexcitatory (cardioacceleratory) center and the cardioinhibitory center that control heart rate and force of cardiac...
contraction. The vasomotor center controls the vessel size and resistance through vasoconstriction and vasodilation.

An increase in blood pressure prompts the baroreceptors to signal the brainstem to alter heart function and vessel size to decrease the blood pressure. The cardio-inhibitory center responds by sending parasympathetic nervous system impulses that cause the heart to decrease heart rate and myocardial contractility. A decrease in myocardial contractility decreases stroke volume. A decrease in stroke volume and heart rate decreases cardiac output. A decrease in cardiac output decreases the blood pressure. The vasomotor center responds by sending sympathetic impulses to dilate the blood vessels. Vasodilation increases the vessel diameter and decreases the systemic vascular resistance, which decreases the blood pressure.

A decrease in blood pressure prompts the baroreceptors to signal the brainstem to alter heart function and vessel size to increase the blood pressure. The cardioexcitatory and vasomotor centers send out sympathetic nervous system impulses to increase the heart rate and myocardial contractility and to constrict the vessels. The increase in heart rate increases the cardiac output. The increase in myocardial contractility increases the stroke volume, which increases the cardiac output. An increase in cardiac output increases the blood pressure. Vasodilation decreases the vessel diameter and increases the systemic vascular resistance, which increases the blood pressure.

**Chemoreceptors.** As previously discussed, the chemoreceptors monitor the content of oxygen, carbon dioxide, hydrogen ions, and the pH of the blood (Figure 8-16). The greatest stimulation to change the blood pressure occurs when the oxygen content in arterial blood decreases. An increase in the carbon dioxide level, resulting in a decrease in the pH value (more acid) has a much lesser effect on the blood pressure. When the oxygen content in the arterial blood falls, carbon dioxide level increases, or pH decreases (more acid in the blood), the brainstem triggers the sympathetic nervous system through the cardioexcitatory center and vasomotor centers to increase the blood pressure by increasing the heart rate, myocardial contractility, and vasoconstriction. The increase in blood pressure is intended to improve the delivery of oxygen to the brain cells and to remove more carbon dioxide. These changes account for the signs you may observe as an EMT. Hypoxia may produce pale, cool skin and an increase in heart rate. The pale, cool skin is from vasoconstriction, and the increase in heart rate is from sympathetic stimulation of the SA node.

A decrease in blood pressure and oxygen content in the blood will also trigger the release of a whole cascade of hormones from different endocrine organs in the body. This will be discussed in greater detail in Chapter 15, “Shock and Resuscitation.”

Maintaining aerobic metabolism is essential for the cells, the organs, and the patient to survive. To summarize, in order to maintain aerobic metabolism of cells, the following must be adequate:

- Oxygen content in ambient air
- Patency of the airway

- Minute ventilation
  - Ventilatory rate
  - Tidal volume
- Alveolar ventilation
  - Ventilatory rate
  - Tidal volume
- Perfusion in the pulmonary capillaries
  - Venous volume
  - Right ventricular pump function
- Gas exchange between the capillaries and the alveoli
- Content of blood
  - Red blood cells
  - Hemoglobin
  - Plasma
- Cardiac output
  - Heart rate
  - Preload
  - Stroke volume
  - Myocardial contractility
  - Afterload
- Systemic vascular resistance
  - Sympathetic nervous system stimulation
  - Parasympathetic nervous system stimulation
- Gas exchange between the capillaries and the cells

**FIGURE 8-16** Chemoreceptor function vis-à-vis content of the blood.

SUMMARY

The most fundamental purpose of your emergency care is to restore or sustain perfusion of cells with oxygen and glucose. With adequate delivery of oxygen and glucose, the cells can maintain aerobic metabolism resulting in the production of water, carbon dioxide, and ATP for energy. With adequate perfusion and ventilation, carbon dioxide can be effectively eliminated through exhalation. A shift to anaerobic metabolism occurs when oxygen is not made available to cells during metabolism, which results in the production of lactic acid as the primary by-product. Acid can have a detrimental effect on cell structure and function.

The key to constant delivery of an adequate supply of oxygen and glucose to cells and the elimination of carbon dioxide and other waste products of metabolism is to establish and maintain an adequate and effective airway, ventilation, oxygenation, gas exchange at both the alveoli and cells, transportation of gases in the blood, blood volume, cardiac function, and blood pressure. An alteration in any one of these components can result in poor perfusion and cellular hypoxia.

Case Study Follow-up

Scene Size-up

You have been dispatched for a 50-year-old male patient who has been stabbed by his wife. The wife is in police custody and the scene is safe to enter. The daughter leads you to an enclosed back porch where you find the patient lying on his side in a pool of blood. Suddenly, a dog rushes from the house and begins barking ferociously. The daughter yells, “Winston! Go back inside the house!” You ask the daughter to take Winston into the house and place him in a room and close the door to secure him.

Patient Assessment

The patient is moaning in pain and clutching his abdomen. You ask the patient his name to determine the level of responsiveness. He states, “Paul—my name is Paul. I can’t believe she stabbed me. I just wanted to watch the football game in peace.” From his response, you gather that he is alert, oriented to his name, has an open airway, and is breathing adequately.

You note that the patient is breathing at a rate of 24/minute and slightly shallow. You think that his minute ventilation appears to be slightly increased because of an increased ventilatory rate; however, you want to be sure that his alveolar ventilation is also adequate. His chest is rising and falling adequately with each breath; thus, he appears to be moving enough tidal volume to sustain the alveolar ventilation. His radial pulse is barely palpable and his skin is pale, cool, and clammy. You expect that the skin is pale, cool, and clammy as a result of vasoconstriction occurring from sympathetic nervous system stimulation and circulating epinephrine and norepinephrine to maintain the blood pressure. The weak pulse is likely due to a loss of volume, a decreased preload, and a decreased cardiac output and intense peripheral vasoconstriction.

His heart rate is 122 bpm. You think that the heart rate is elevated as an attempt to raise the cardiac output and to increase or maintain the blood pressure. Your partner places him on a nonrebreather mask at 15 lpm in an attempt to fill the alveoli with a high concentration of oxygen to attach as many oxygen molecules as possible to the binding sites on the hemoglobin in the blood.

You expose the patient and perform a quick examination of his body from head to toe, looking for other injuries and signs. During the assessment, he complains, “My belly hurts really bad.” The abdomen is rigid and tender when you palpate it. You suspect this is from blood loss in the abdominal cavity. Your partner assesses the vital signs: BP 102/88 mmHg, heart rate 122 bpm, respiration 24/minute, and skin pale, cool, and clammy.

The pulse pressure appears to be narrow. You do a quick mental calculation and determine that 25 percent of 100 is 25; thus, the pulse pressure should be around 25 mmHg or greater. You quickly subtract the diastolic blood pressure from the systolic and determine that the pulse pressure is 14 mmHg. You suspect the narrow pulse pressure is correlated with blood volume loss from the stab wound to the abdomen, causing a drop in preload and a decrease in stroke volume and cardiac output, causing the systolic blood pressure to decrease. The baroreceptors sensed the decrease in pressure inside the aortic arch and carotid sinuses and sent impulses to the brainstem to trigger the sympathetic nervous system to raise the blood pressure. Based on the formula $BP = CO \times SVR$, you suspect the increased heart rate is an attempt to raise the cardiac output, and the pale, cool, clammy skin is a sign of vasoconstriction in an attempt to increase the systemic vascular resistance. The decrease in cardiac output and increase in systemic vascular resistance are creating the narrow pulse pressure.
**Case Study Follow-up**

You cover the stab wounds to the abdomen and prepare the patient for transport. En route you continue to reassess the patient, contact the receiving medical facility, and provide a radio report. Once at the medical facility, you provide an oral report to the physician and complete your transfer of care. You clean up the ambulance and prepare for your next call.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

---

**IN REVIEW**

1. Describe the difference between aerobic metabolism and anaerobic metabolism.
2. Define FiO₂ and FDO₂.
3. Describe how the content of gases in the ambient air affects the oxygenation status of the patient.
4. Describe possible causes of airway obstruction at the nasopharynx, oropharynx, pharynx, and larynx.
5. Describe the mechanical process of inhalation and exhalation.
6. Describe how Boyle’s law affects ventilation.
7. List and describe the role of the respiratory centers located in the brainstem.
8. List, identify the location, and describe the role of the two different types of chemoreceptors.
9. Describe the ventilation/perfusion ratio and its relationship to cellular hypoxia.
10. Describe the transport of oxygen in the blood.
11. Describe the transport of carbon dioxide in the blood.
12. List the components of the blood and describe the function of each component.
13. Define hydrostatic pressure and plasma oncotic pressure.
14. List, define, and describe the factors that determine the cardiac output, systemic vascular resistance, and blood pressure.
15. Describe the influence of the sympathetic nervous system and parasympathetic nervous system on the cardiac output and blood pressure.
16. Define microcirculation and describe how it affects blood pressure and perfusion.
17. Identify the location and describe the role of the baroreceptors.
18. Discuss how the chemoreceptors influence changes in blood pressure.

---

**CRITICAL THINKING**

You arrive on the scene and find a 28-year-old construction worker who has sustained a large, gaping laceration to his left upper leg. Blood is spurting from the wound. The patient only responds with moans when you yell his name. His respiratory rate is 26/minute. His radial pulse is absent. His skin is extremely pale, cool, and clammy. His blood pressure is 98/76 mmHg and heart rate is 134/minute.

1. In order to determine if his ventilation is adequate, what else must you assess?
2. Based on the ventilation/perfusion ratio, why would the cells in the patient become and remain hypoxic?
3. Why is the patient responding so poorly?
4. How is the spurting blood affecting the perfusion of the cells?
5. What is causing a decrease in the systolic blood pressure?
6. Is the pulse pressure narrow? If so, describe why.
7. Why is the skin pale, cool, and clammy?
8. Why is the heart rate 134 bpm?
9. Are the cells of this patient likely undergoing aerobic or anaerobic metabolism? Why?
10. Why does the patient have such a lack of energy?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Life Span Development**

**COMPETENCY •** Applies fundamental knowledge of life span development to patient assessment and management.

**OBJECTIVES •** After reading this chapter, you should be able to:

9-1. Define key terms introduced in this chapter.
9-2. Identify the age ranges associated with each of the following terms:
   - a. Neonate
   - b. Infant
   - c. Toddler
   - d. Preschooler
   - e. School age
   - f. Adolescent
   - g. Early adulthood
   - h. Middle adulthood
   - i. Late adulthood

9-3. Describe the physiological changes that occur immediately after birth.
9-4. Discuss the key physical and psychosocial characteristics of individuals in each of the following age groups:
   - a. Neonates and infants
   - b. Toddlers
   - c. Preschool-age children
   - d. School-age children
   - e. Adolescents
   - f. Early adulthood
   - g. Middle adulthood
   - h. Late adulthood

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- adolescent p. 196
- fontanelles p. 193
- infant p. 191
- life expectancy p. 198
- maximum life span p. 198

- menopause p. 198
- neonate p. 191
- nocturnal enuresis p. 195
- preschooler p. 194
- puberty p. 196

- reflex p. 192
- school-age child p. 195
- toddler p. 194
Case Study

The Dispatch
EMS Unit 112—respond to 408 Windsor Avenue—you have a 16-year-old male patient who is complaining of difficulty urinating. Time out is 1345 hours.

Upon Arrival
Upon your arrival, a 37-year-old woman answers the door. She states that her son has complained that it hurts when he urinates and that she wants him checked out. As you enter the back bedroom, you find an alert and oriented 16-year-old male text-messaging on his cell phone. He yells at his mother and asks why she called the ambulance. She yells back and tells him that he is going to go to the hospital.

How would you proceed to assess and care for this patient?
During this chapter, you will learn about the stages of life span development and how to apply this knowledge to your assessment and emergency care for a patient. Later, we will return to the case and apply the knowledge learned.

INTRODUCTION
Throughout the course of a lifetime, people experience changes, both physical and psychosocial. Although each individual matures at a different rate, most changes normally occur within a specific period of life. As an EMT, you will assess and treat patients who are in various life stages. You will need to incorporate your knowledge of what is expected for each stage into your patient assessment and management. Life span development begins at conception; however, prenatal development will be discussed later in Chapter 37, "Obstetrics and Care of the Newborn."

LIFE SPAN DEVELOPMENT
The life stages discussed in this chapter are infants, toddlers, preschool-age children, school-age children, adolescents, and adults at early adulthood, middle adulthood, and late adulthood. For each group, normal vital signs are discussed. Normal vital signs for the various age groups are summarized in Table 9-1.

Neonates and Infants
The term neonate refers to the child from birth to 1 month of age (Figure 9-1a ■), while the term infant refers to the

</table>
child from 1 month to 1 year of age (Figure 9-1b ■). During this period, a child undergoes some of the most rapid growth and development.

**Vital Signs**

At birth, the neonate has a respiratory rate of 40–60 breaths per minute and a tidal volume of only 6–8 mL/kg. His respiratory rate will drop to 30–40 breaths per minute after a few minutes of life. By the age of 1 year, his respiratory rate will be 20–30 breaths per minute and the tidal volume will increase to 10–15 mL/kg. At birth a neonate’s heart rate is normally 140–160 beats per minute. Within the first 30 minutes after birth, the baby’s heart rate decreases to 100–160 beats per minute. Then the heart rate will normally settle to around 120 beats per minute and remain that way or will slightly decrease throughout infancy. The average systolic blood pressure of an infant increases from 70 mmHg at birth to 90 mmHg by 1 year of age. An infant’s temperature is normally 98°F–100°F, which is the thermoneutral range. In general, as an infant ages his heart rate and respiratory rate become lower and his systolic blood pressure becomes higher.

**Physiological Changes**

At birth the neonate normally weighs 3.0–3.5 kg and the head accounts for 25 percent of the total body weight. The initial birth weight of the neonate normally drops 5–10 percent in the first 2 weeks of life, but the lost weight is normally regained shortly thereafter. The baby’s weight will continue to increase throughout infancy with proper nutrition. Infants require breast milk or formula to meet their nutritional needs. As his first year progresses, the infant will be able to consume other soft foods without yet having teeth. During infancy, the primary teeth will begin to emerge, and the baby will be slowly introduced to solid foods.

A baby’s pulmonary system also undergoes changes throughout infancy. An infant’s airways are shorter, narrower, less stable, and more easily obstructed than those of an adult. This can make him more easily susceptible to airway obstructions. Until 4 weeks of age, infants are primarily nose breathers. They have fewer alveoli with decreased collateral ventilation. Their lung tissue is also fragile and is prone to trauma from pressure. It is important for the EMT to be mindful of this when manually ventilating an infant. Infants also have immature accessory muscles. This makes them easily susceptible to early fatigue from labored breathing. The infant’s less rigid chest wall and more horizontally placed ribs promote diaphragmatic breathing. Therefore the EMT should examine both the chest and the abdomen when assessing an infant’s respiration. If an infant’s respiratory rate is rapid, it can lead to rapid heat and fluid loss. The EMT can help to prevent some of the heat loss by keeping the baby warm and dry.

The infant’s immune system is also immature. Most of the neonate’s immunity is based on antibodies that he received through the placenta from his mother during pregnancy. This is called passive immunity and is normally retained through the first 6 months of life. Babies who are breast-fed may also receive antibodies from their mother’s breast milk and will thus retain immunity as long as breast-feeding continues. Because infants are more susceptible to infections and diseases, it is important for them to be immunized early. Childhood immunizations normally begin after birth and should continue to be provided at various times throughout the child’s development.

The infant’s nervous system allows him to have normal movement and sensation. Infants also have special reflexes, or instantaneous and involuntary movements, that result from a stimulus at birth. These reflexes include blinking, startling, rooting, sucking, swallowing, stepping, gagging, and grasping reflexes. Their very strong and coordinated sucking and gag reflexes help them survive. They also have well-flexed extremities that move equally when the infant is stimulated. An EMT should look for symmetrical movement when assessing an infant. Infants are able to sense pain and touch. Although they are not capable of localizing pain, it is important to consider that an infant may be experiencing pain if he is crying. As the baby grows, his response to pain will become more specific.
Babies are born with fontanelles, or soft spots on the skull that allow the head to be compressed and pass through the birth canal during delivery. The fontanelles also allow room for the rapid expansion and growth of the brain during infancy. The posterior fontanelle closes at 3 months and the anterior fontanelle closes between 9 and 18 months. The EMT should never press on the fontanelles. The fontanelles may provide the EMT with an indirect estimate of hydration. Normally, the fontanelles will be level to the skull. If the child is dehydrated, the fontanelles may appear depressed or sunken in relation to the rest of the skull.

The bones in the baby’s musculoskeletal system will grow throughout infancy. As the infant grows, he will be able to perform more activities. The EMT should know what activities are normally present at various stages of infancy.

By 2 months, an infant should be able to do the following:
- Track objects with his eyes
- Focus on objects 8–12 inches away
- Recognize familiar faces
- Display primary emotions and facial expressions
- Hear and recognize some familiar sounds and voices
- Move in response to stimuli

By 6 months, the infant should be able to do the following:
- Sit upright in a high chair
- Make one-syllable sounds (e.g., ma, mu, da, di)
- Raise and support his upper body when he is on his stomach
- Grasp and shake hand toys
- Push down on his legs and feet when held over a firm surface
- Follow moving objects with his eyes
- Recognize familiar objects at a distance
- Begin to babble and try to imitate familiar sounds

By 12 months, the infant should be able to do the following:
- Walk with help
- Know his own name
- Sit without assistance
- Crawl and creep on his hands and knees
- Put objects into containers
- Poke objects with fingers
- Respond to simple requests and “no”
- Say “mama” or “dada”
- Imitate some words, gestures, and facial expressions
- Begin to use objects like brushes, cups, or phones correctly
- Finger feed himself

Every child develops at his own pace. However, if an infant is not able to perform these tasks within the normal time frame, the infant should be evaluated by a physician. EMTs should know what types of movements and activities are expected during each of these periods so they can better assess the pediatric patient and understand his responses.

**Psychosocial Changes**

Just as the infant experiences many physical changes, he will also develop psychosocially throughout infancy. The relationships built during this period most often revolve around the infant’s parents and primary caregivers. The parents are responsible not only for meeting the infant’s physical needs but also for providing a stable home filled with love and affection. Children who lack fulfillment of any of their physical, emotional, or psychological needs are less likely to become healthy self-reliant adults. Infants bond with the people who meet their needs.

As an EMT you may encounter different responses when you attempt to take an infant away from his parent. In most cases, the infant will protest and act as if in despair and withdrawal when separated from his caregiver. To him, you are not his caregiver and he will tend to be afraid of you. Crying and restlessness may persist even after the child is returned to the parent. If the infant does not seem anxious or upset when separated from his parent, the EMT should consider underlying causes that may be affecting the infant’s response.

Crying is how infants communicate with the world around them. Although the EMT may not recognize a difference in an infant’s cry, the parent or caregiver should be able to. An infant normally cries in response to a basic need, anger, or pain. The basic cry normally indicates that the child is hungry, wet, or tired. Once this need is met, the infant normally does not continue to cry. An infant may also cry as a result of being angry. This type of cry can usually be noted by the EMT who separates the infant from his parent. This type of crying can be avoided if you allow the parent to hold the infant during your assessment. The child may also cry as a response to pain. If the cry persists for a long period of time and all the other needs of the child have been met, the EMT should suspect that something else, such as pain, is contributing to the infant’s response.

By the end of infancy, the baby will have developed relationships with his parents and family. He should be able to recognize his favorite things and people. Some infants may have a favorite toy or other item they can hold that may provide some comfort while you perform your assessment. However, never allow an infant to have anything that could possibly cause an airway obstruction. Smile and speak in a calm voice when assessing a patient in this age group. Try to keep the parents calm, too. Although the infant may not be able to understand what is occurring, he is able to identify changes in emotion and gestures, especially from his parents. If the parent is upset and scared, the infant usually will respond in the same way.
**Toddlers and Preschool-Age Children**

The term **toddler** refers to a child who is 1 to 3 years of age. A **preschooler** is a child who is 3 to 6 years of age (Figures 9-2a and 9-2b). The children in these stages continue to grow physically and psychosocially.

**Vital Signs**

As children age, their heart and respiratory rates tend to decrease while their systolic blood pressure increases. Typically, a toddler will have a normal heart rate of 80–130 beats per minute. He will have a normal respiratory rate of 20–30 breaths per minute. The toddler’s normal systolic blood pressure will range from 70–100 mmHg. The child’s temperature will range from 98.6°F–99.6°F.

Preschoolers typically have a normal heart rate of 80–120 beats per minute. Their respiratory rate is normally 20–30 breaths per minute. The normal systolic blood pressure for a preschooler ranges from 80–110 mmHg.

The body temperature of a preschooler will range from 98.6°F–99.6°F.

**Physiological Changes**

As children get older, they experience more physiological changes. The bones in the musculoskeletal system continue to grow and increase in density. By the end of this period, children will have all of their primary teeth. Toddlers and preschoolers continue to increase their muscle mass, but their weight gain slows down. They normally shed extra fat and become leaner.

In the pulmonary system, the terminal airways continue to branch and the alveoli continue to grow in number. Passive immunity from the mother is lost, which makes the child more susceptible to minor respiratory and gastrointestinal infections. However, the child begins to develop his own immunity, known as active immunity, to common pathogens as exposure occurs. Children in this age group are normally exposed to other children and new environments, which increases the number of infections they typically contract, but it helps them build their own immunities.

The nervous system of toddlers and preschoolers continues to develop quickly. The brain is the fastest growing part of their body, and by preschool age the child’s brain has reached 90 percent of its adult weight. During this period, their development allows for effortless walking and other basic motor skills. These children begin to develop fine motor skills, too, such as using their fingers and hands to manipulate objects and scribble.

Although children are physiologically capable of toilet training by 12 to 15 months, most are not psychologically ready until they reach 18 to 30 months. The average age for toilet training completion is 28 months. Although they are toilet trained, most children will continue to experience bed-wetting at night until they are 6 or 7 years of age.

It is important for the EMT to recognize what activities toddlers and preschoolers are capable of performing. This information may help in identifying what is normal for a child in this age group.

By the age of 3, the child should be able to:

- Walk alone and begin to run
- Pull or carry several toys when walking
- Climb up and down furniture or stairs with minimal support
- Scribble and play with toys
- Recognize names, faces, voices, objects, and body parts
- Find hidden objects
- Sort objects by shape or color

By the age of 5, children should be able to:

- Stand on one foot for more than 10 seconds
- Hop, jump, swing, climb, and do somersaults
- Dress and undress without assistance
School-Age Children
The term school-age child refers to a child between 6 and 12 years of age (Figure 9-3 ■).

Vital Signs
School-age children have normal heart rates ranging from 70–110 beats per minute. Their respiratory rates range from 20–30 breaths per minute. They typically have a systolic blood pressure of 80–120 mmHg. A school-age child’s temperature is normally 98.6°F.

Physiological Changes
As school-age children get older, they continue to grow and change. The bones in the musculoskeletal system continue to increase in density and grow larger. Most children experience some discomfort when this occurs. School-age children lose their primary teeth and replace them with permanent teeth. Their brain function increases in both hemispheres. Children in this age group are normally able to read and write. Although school-age children are able to control their bodily functions better, some still struggle with nocturnal enuresis, or involuntary bed-wetting at night, after the age of 10.

Psychosocial Changes
Most children in this age group attend school and develop relationships outside the home. Because of this, they interact more with adults and other children. Friendships are formed, especially with the same sex, and become more important during this period. Most children in this age group participate in a variety of social activities and develop problem-solving skills. They

• Use forks, spoons, and sometimes knives appropriately
• Count ten or more objects
• Trace and draw pictures

Psychosocial Changes
Toddlers and preschoolers experience many psychosocial and cognitive changes. Language takes the place of crying as the sole form of communication. The basics of language are usually mastered by approximately 36 months, and the child can say single words and make simple phrases and sentences. As the child grows, his language will continue to expand and be refined. By 18 to 24 months, a child can understand cause and effect. Most children develop separation anxiety at approximately 18 months of age. This reaction normally includes the child clinging to the parent or caregiver and crying when the person leaves. By age 5, a preschooler can say his name and address. He can also recall and tell stories using sentences.

Children use play in a variety of ways. They explore new ideas and objects, identify and resolve simple problems, and learn from engaging in different activities. During this period, children are able to play simple games and follow basic rules. Play time also serves as a social outlet and encourages the children to learn and improve their social skills. Many children attend preschool or day care and begin to develop friendships outside their immediate families. Children in this group begin to display competitiveness. Toddlers and preschoolers may express feelings and frustrations they can’t express through play.

When assessing a toddler or preschooler, the EMT should take extra time to communicate with the patient on a level he understands. Children take language literally, so phrases like “take your blood pressure” should be replaced with a phrase that can be interpreted literally, such as “measure your blood pressure.” It also helps if you allow the child to touch the equipment before you use it and demonstrate on a parent how the equipment will be used. Techniques like these will help decrease the child’s anxiety and increase the trust he will have in you. Never lie to a child, because you will not regain his trust during the short period you will see him. Allow the parent to stay with the child during the assessment if possible. This will also help alleviate some of the child’s fears and provide you with more information pertinent to the situation.

School-Age Children
The term school-age child refers to a child between 6 and 12 years of age (Figure 9-3 ■).
are capable of fundamental reasoning and problem solving, but have not developed the insight to do so in all situations.

School-age children develop their own self-concept, that is, a personal concept of who they are. These children compare themselves with others to help determine their own values and to seek the approval of others. School-age children also begin to develop a sense of self-esteem and morals. They understand how to obey rules and avoid punishment. School-age children understand concepts associated with pain, illness, death, and loss, but most are still uneasy or scared when those situations occur. They will usually turn to a parent or other adult or to a trusted friend to help them cope with their fears.

Most school-age children identify EMTs, firefighters, and law enforcement officers as people who can help them in a crisis. They may actually have unrealistic expectations about what you are able to do, but assure them that you are doing everything you can to help them or their family member. Make sure you communicate at a level they can understand.

Adolescence

An adolescent is a child between 12 and 18 years of age (Figure 9-4). Although most adolescents want to feel and be treated as adults, they are not adults and are continuing to experience physiological and psychosocial changes throughout this period.

Vital Signs

Adolescents have normal heart rates ranging from 55–105 beats per minute. Their normal respiratory rate ranges from 12–20 breaths per minute. They typically have a systolic blood pressure of 100–120 mmHg. An adolescent’s temperature is normally 98.6°F.

Physiological Changes

Most adolescents will experience a rapid 2- to 3-year growth spurt. Their muscle mass and bone growth and development are nearly complete by the end of this period. The adolescent’s growth spurt begins distally with the enlargement of the feet and hands and progresses along the extremities. In the final stages of adolescence, the chest and trunk enlarge. Girls are mostly done growing by age 16, while boys are mostly done by age 18.

During this period, adolescents go through puberty, the period in which the sexual organs mature and reproductive maturity is reached. Girls usually begin puberty around age 10, which is about 2 years before most boys. Primary and secondary sexual development occurs. Endocrine changes occur and specific hormones are released into the adolescent’s bloodstream. During this period, males grow facial, pubic, and axillary hair. They also develop a deeper voice. Their shoulders broaden and their muscles become larger. The adolescent male’s penis and testes also increase in size and the adolescent has erections that result in the ejaculation of semen. Females begin menstruation and their breasts enlarge. They also grow pubic and axillary hair. Their hips normally widen and the waist gets smaller.

Psychosocial Changes

The many biological, social, and emotional changes that occur during adolescence can cause family conflicts. Most of these conflicts revolve around the adolescent and his parents. Adolescents become more argumentative and more aware of the shortcomings of others. They also believe that they are the focus of others’ attention and that they are invulnerable. As a result, many participate in risky behaviors.

Adolescents desire to be treated as adults although most are not capable of making their own medical decisions. (See Chapter 3, “Medical, Legal, and Ethical Issues.”) Adolescents want privacy, and most will prefer if their parents are not present during the patient interview. If possible, interview the adolescent in private. Interview them in the same way you would an adult, but remember that you should obtain the parent’s consent before doing so. Adolescents may be more willing to disclose pertinent medical information or self-destructive behaviors if their parents are not present.

During this time, adolescents develop their identity. They often try to imitate others and experiment with alternative identities in an attempt to find their
own. Peer pressure increases during this stage. Self-consciousness increases and adolescents desire more independence and responsibility. They begin to make decisions that will influence their careers and their futures.

Adolescents understand that there are consequences to their actions and are capable of discerning what is right and socially acceptable and what is wrong. Antisocial behavior peaks around eighth or ninth grade. Some adolescents begin to participate in self-destructive behaviors such as tobacco, alcohol, and/or illicit drug use. These types of behaviors can cause both physical and psychosocial problems for the adolescent. Depression and suicide are more common in this age group than in any other.

Adolescents are also very concerned with body image. How they look and feel about themselves has a profound impact on their sense of identity and self-esteem. They make continual comparisons between themselves and their peers and often look to outside sources for what a “perfect body” should be like. Because of this, eating disorders within this age group are common. Bulimia (eating and deliberately throwing up) and anorexia nervosa (not eating enough to meet nutritional needs) in order to control weight are more frequently identified in females; however, these disorders are also becoming more common among males. These eating disorders can cause both psychological and physical problems and occasionally become severe enough to be life threatening.

During adolescence, both males and females experience an increased interest in the opposite sex and begin dating and/or participating in sexual activity. Because their bodies and sex cells have matured, they are capable of reproduction. Some adolescents choose to abstain from sexual activity during this period. Many adolescents who engage in sexual activity do not use condoms or otherwise practice safe sex. Some may feel they are invulnerable to the risks, while others may be embarrassed to ask for their partner’s sexual history or simply get too carried away to be pragmatic. Participation in unprotected sexual activities increases the risk of acquiring sexually transmitted diseases as well as the risk of pregnancy.

**Early Adulthood**

Early adulthood is defined as the stage of development when a person is 20 to 40 years of age (Figure 9-5).  

**Vital Signs**

The average heart rate for a person in early adulthood is 70 beats per minute. Average respiratory rate is 16–20 breaths per minute. Average blood pressure is 120/80 mmHg. Normal temperature is 98.6°F.

**Physiological Changes**

During early adulthood, all body systems are operating at optimal levels. Most people reach peak physical condition between 19 and 26 years of age. Because of their excellent physical condition, they are capable of risky activity, and hence accidents are the leading cause of death in this age group. Once young adults reach their peak, however, their physical condition begins to slow down. They gain weight, store fat, and experience decreased muscle tone. Their spinal disks settle. During this period, adults also develop lifelong habits and routines that will impact the quality of their health and life.

**Psychosocial Changes**

Upon entering early adulthood, people generally take on more responsibility and become more independent. Many young adults choose to leave their parents’ homes and make homes of their own. During this period, most people develop both romantic and affectionate relationships. Many young adults marry and begin new families. Childbirth is most common in this age group. Their new families provide new challenges and stress for the early adults. It is also during this time that many adults finish school and find a career. They experience the highest levels of job stress during this period. Early adults are more capable of coping with their stress than when they were younger. This period is less associated with psychological problems related to well-being than other age groups.

**Middle Adulthood**

Middle adulthood is the stage of development when a person is 41 to 60 years of age (Figure 9-6).  

**Vital Signs**

The average heart rate for a person in middle adulthood is 70 beats per minute. Their average respiratory rate is
16–20 breaths per minute. They have an average blood pressure of 120/80 mmHg, and their temperature is normally 98.6°F. There are no significant changes in normal levels from early adulthood.

**Physiological Changes**

During middle adulthood, the body is still functioning at a high level but with varying degrees of degradation. Body systems are beginning to experience more changes as a result of disease and lifestyle decisions. Adults in this stage are more susceptible to chronic illnesses and diseases like diabetes and arthritis.

It is usually during middle adulthood when cardiovascular health becomes a concern. Cardiac output decreases throughout this period. Cholesterol levels increase. This makes people more susceptible to cardiovascular diseases. Cancer is also a concern and strikes this age group frequently. Screenings for various types of cancers are recommended to those in this age group.

Middle-aged adults continue to gain weight easily, while controlling weight becomes more difficult. Many individuals have vision changes and require corrective lenses to see properly. Because of environmental and physical changes, most do not hear as well as they did during early adulthood.

Normally, women in their late 40s and 50s will go through menopause, or the permanent end of menstruation and fertility. Many women during this period are prone to a decrease in height as a result of osteoporosis.

**Psychosocial Changes**

During middle adulthood, people tend to approach problems more as challenges than as threats. This is the period when many individuals reach their goals and try to find ways to help younger generations. Some adults experience a period of self-questioning if they have not been able to accomplish their goals. These adults have experienced many different problems within previous stages of life, and have developed coping strategies that can be useful throughout the remainder of adulthood. This age group is aware of the limits of time, and many formulate new goals for the remainder of their lives.

Many adults focus on others rather than themselves during this stage. Because of this, some may delay seeking help for health issues. Many of these adults are burdened by financial commitments both for elderly parents and for young adult children. Transitions in parenting also occur during this period. As the children leave the home, some adults experience a feeling of loss known as empty nest syndrome; others embrace the extra time they didn’t have before. Sometimes, grown-up children return home because of economic or social reasons. This can be both positive and negative for the families. It is also during this period that many adults become grandparents.

**Late Adulthood**

Late adulthood is the stage of development when a person is 61 years of age and older (Figure 9-7 ●).

**Vital Signs**

The heart rate, respiratory rate, and blood pressure in late adulthood depend on the person’s physical and health status. Underlying diseases, poor physical conditioning, and some medications can alter the vital signs for these patients. Normal temperature in late adulthood is 98.6°F.

**Physiological Changes**

The maximum life span, which is the theoretically longest period of time for an organism to live, is 120 years for a human being. However, an individual’s life expectancy is the average years of life remaining based on the individual’s year of birth. Almost all individuals will die from diseases or accidents before reaching the maximum life span. The incidence of diseases and illnesses continues to increase with age. During late adulthood, most body systems continue to become less efficient.
The cardiovascular system undergoes several changes in late adulthood. The efficiency of circulation decreases. The blood vessels within the cardiovascular system thicken, which results in increased peripheral resistance, which in turn reduces blood flow to the organs. The workload and size of the heart increase, which puts additional demands on the myocardium. Many older adults have heart problems and diseases that contribute to the additional workload on the heart. The myocardium is less able to respond to exercise, and tachycardia is not well tolerated in this age group. The functional blood volume is also decreased in late adulthood.

The respiratory system also develops changes in the mouth, nose, and lungs during late adulthood. The chest wall and bone structure weaken and make coughing ineffective. The elasticity of the diaphragm and the lung capacity of these adults are diminished. Metabolic changes and lifelong exposure to pollutants have diminished the lung capacity and diffusion of the gases through the alveoli.

The nervous system also changes during late adulthood. The brain gets smaller and these adults lose neurons, which causes problems with memory, balance, and movement. The sleep cycle may be disrupted, and many older adults experience sleep problems. Reaction time to various stimuli is decreased, and it takes longer to respond than before. This makes older adults more prone to falls or injury.

These adults experience many sensory changes. They lose taste buds, which results in a diminished sense of taste. Their olfactory senses are also diminished. They experience diminished pain perception and diminished kinesthetic sense. Adults in this period also experience hearing loss and their visual acuity is decreased. Many adults need corrective lenses and hearing aids to help compensate for these sensory losses.

The endocrine, reproductive, and renal systems are also affected in late adulthood. These adults have decreased metabolism and insulin production. Some adults in late adulthood may have underlying problems resulting from diabetes. The reproductive organs atrophy in women during this developmental stage. There is a 50 percent nephron loss within the kidneys, and the amount of abnormal glomeruli increase during this period. Adults in late adulthood have a decreased elimination of urine from the renal system. Problems with hydration are common in this age group.

Older adults experience changes to the mouth, teeth, and saliva during this period. Many adults lose permanent teeth and must use dentures. This can lead to changes in diet that could result in vitamin and mineral deficiencies. Their ability to chew their food can be impaired and may result in possible airway obstructions. Dentures, or the loss of teeth without them, may influence speech and communication. The gastrointestinal system functions less efficiently and gastrointestinal secretions are decreased. The rate of absorption of minerals, foods, and medications also changes, and many adults suffer from constipation during this period.

Because of the nature of EMS, many older patients that you are called to treat will be experiencing not only the current emergency but one or more chronic illnesses as well. However, there is a wider variation of health status in this age group than in any other. While some at this time of life have serious mental or physical problems, many others maintain good mental and physical health and lead active lives throughout their 60s, 70s, 80s, and even their 90s. When dealing with an older adult, be aware of the possibility of underlying ill health, but do not assume that every older patient has chronic physical or mental deficits.

**Psychosocial Changes**

During late adulthood, people face new challenges that may not have been present throughout the previous stages. In some cultures, wisdom is attributed to age. The experiences and behaviors developed throughout their lifetime have influenced who they have become. These adults tend to reflect on their lives and generally are either satisfied with the outcome or have regrets that may lead to depression or despair.

Some adults have families and friends who can provide support during this period, while many others do not. Even those who have support networks may feel alone and isolated at this stage.

Although many adults have lived in their homes for a great portion of their lives, many during late adulthood must make decisions about moving. Many older adults live in assisted-living communities that can help provide social, emotional, and physical support to their residents. However, these communities are expensive and many individuals must sell their homes and possessions in order to reside there, while many others cannot afford them at all. Some remain at home or may move in to a family member’s home. Sometimes the decision to move is based on the financial burdens associated with living alone and no longer working. Many adults during this period live on fixed incomes and must make difficult decisions about how to manage their finances.

Because older adults have been independent and self-reliant for most of their lives, some may feel ashamed or otherwise reluctant to give up their independence and ask for assistance. Combined with many of the physical changes and illnesses they may have, this can lead to a decline in the older adult’s well-being and sense of self-worth. Many find themselves not capable of performing activities that they once performed easily. Many of these adults also experience the death or dying of their spouses or companions. This may leave them feeling more alone and isolated than before and may cause them to think more about their own death.

However, while there are many psychosocial challenges associated with aging, the majority of older adults are able to remain in their own homes and lead rewarding lives. Most do not need to go to a nursing home, to an assisted-living facility, or to live with relatives until very advanced age or at all.
Chapter Review

SUMMARY

People develop and change continuously throughout their life span. These changes are both physical and psychosocial in nature. It is important to understand the different stages of life and to know what is normal for each stage. It is also important to understand what changes and challenges your patients may be experiencing during each stage of development. Such understanding can help you identify your patient's needs and appropriately modify your assessment and management approach. The stages an EMT should be knowledgeable about are infancy, toddlerhood, preschool age, school age, adolescence, early adulthood, middle adulthood, and late adulthood.

Case Study Follow-up

Scene Size-up
You have been dispatched to a 16-year-old male patient complaining of difficulty urinating. As you arrive on the scene, you are greeted by a 37-year-old woman who answers the front door. She states that her name is Linda Shively and that her 16-year-old son, Jeremiah, has been complaining that it hurts when he urinates. She states that she wants him checked out and taken to the local emergency department. She leads you into the back bedroom of a neat and orderly residence. As you enter the back bedroom, you see a young man on his bed.

Patient Assessment
The patient, a 16-year-old male who is dressed in jeans and a T-shirt, is actively text-messaging on his cell phone as you approach him. As you say "Hello," he begins to yell at his mother and asks her, "Why did you call the ambulance?" His mother yells back that he is going to go to the hospital. Because you know conflict between adolescents and their parents is normal, you ask your partner to take Mrs. Shively into another room to gather the patient's medical history.

The teenager identifies himself as Jeremiah Shively and states that he really doesn't want to go to the ED. He is alert and oriented. His airway is open and he is breathing adequately at 12 breaths per minute. His pulse is 60 beats per minute and his skin is warm and dry. His blood pressure is 110/74 mmHg. His vitals appear within normal ranges for his age.

You begin your patient interview by introducing yourself and explaining that you are there to help him. You know that adolescents want to be treated as adults. You also understand that Jeremiah will be more likely to disclose information to you in private than with his mother in the room. You ask him if he is having any problems. He continues to text-message and says, "No." You state his mother called and said he was having pain when he urinates. He then replies, "That's just what I told her."

You attempt to develop a good rapport with Jeremiah. You ask him again if he is having any problems either urinating or in general. This time he states that he is not having much pain when he urinates, but that he does have itching and redness around his genitals. Because you are aware that many adolescents are sexually active, you know that you will need to ask more personal questions that may potentially embarrass the teen. As you proceed to obtain a history from him, he confides in you that he has been sexually active. You ask him directly about his sexual history, and he states that he has had unprotected sex with several partners. You know this type of behavior puts him at risk for sexually transmitted diseases.

You ask Jeremiah if you may examine him, and he agrees. You perform a complete physical assessment, noting nothing out of the ordinary for Jeremiah's age except in the genital area, as he stated. You explain that his mother wants him to be evaluated at the local hospital and that he should be assessed and treated by a physician. You also explain the consequences of not seeking medical treatment for his current condition. Knowing that adolescents are capable of reasoning and understanding the consequences of their actions, you ask him if he will go with you to the hospital. Although he is a minor and cannot provide you with full consent—or refusal—for treatment, it is important that you make him feel that he has an active role in his care. You understand that if you address Jeremiah as you would an adult, he will most likely cooperate and agree to go; however, if he doesn't agree you will need to explain how his mother's request for treatment and transport must be honored. Fortunately, Jeremiah acknowledges that he should seek medical attention and agrees to go with you to the emergency department.

Transport and Transfer of Care
As you prepare Jeremiah for transport, his mother enters the room with your partner. Your partner provides you with the information he has received from Mrs. Shively. In order to help maintain patient rapport and avoid other potential conflicts between the mother and son, you
inform Mrs. Shivley that you have talked to Jeremiah and he has agreed to go with you to the ED and to be seen by a physician as she asked. You ask her if she would like to accompany your partner in the front of the ambulance if she would prefer to meet you at the receiving facility. Mrs. Shivley elected to meet you at the receiving facility and leaves the scene after you have. You assure her that you will provide proper care and treatment for her child en route to the receiving facility.

En route you continue to reassess Jeremiah. You also call the receiving facility and give a verbal report to the triage nurse on duty. Upon arrival at the emergency department, Mrs. Shivley meets you at the door. As she proceeds to go in and register Jeremiah, you transfer care to the ED physician and provide him with a complete report about the call, your assessment findings, and your management. You then place Jeremiah in the hospital cubicle he has been assigned to. You again suggest to Jeremiah that he speak to the physician about his risky sexual behaviors.

When Mrs. Shivley comes into the cubicle, you finish your documentation and ask her to sign your patient care report. You wish them both the best as you leave the cubicle. As you depart the ED, you make sure to leave a copy of your documentation with the staff.

**Case Study Follow-up continued**

**IN REVIEW**

1. Describe each stage of development with regard to vital signs, physiological changes, and psychosocial changes.
2. List the normal vital signs for infants, toddlers, preschoolers, school-age children, adolescents, and adults.

**CRITICAL THINKING**

You arrive on the scene and find a 2-year-old child in her father’s arms. The father is crying and obviously very upset. He states that he thinks his daughter may have eaten some food that was left out overnight. He explains that he was washing the dishes a couple of minutes ago when he saw her drink from her old cup and he noticed some of the food was missing that had been left on her plate from supper the evening before. The patient is alert and watching your every move. As you approach her, she clings to her father and begins to cry. She has a foul odor on her breath and her dress is wet. Her respirations are 26 per minute with good chest rise. Her radial pulse is regular at a rate of 110 beats per minute. Her skin is warm and dry.

1. Was the young girl’s reaction toward you normal for her age?
2. What can you do to help build a good rapport with the patient?
3. List activities that a child should be capable of performing at 1, 3, and 5 years of age.
4. Based on her developmental stage, what vital signs did you expect this patient to have?
5. How will you adjust your assessment techniques to meet this patient’s needs?
6. What would you say to the father in this scenario?
PART 5 Airway Management, Respiration, and Artificial Ventilation

CHAPTER 10

Airway Management, Artificial Ventilation, and Oxygenation

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

STANDARD • Airway Management, Respiration, and Artificial Ventilation (Content Areas: Airway Management; Respiration; Artificial Ventilation)

COMPETENCY • Applies knowledge (fundamental depth, foundational breadth) of general anatomy and physiology to patient assessment and management in order to assure a patent airway, adequate mechanical ventilation, and respiration for patients of all ages.

OBJECTIVES • After reading this chapter, you should be able to:

10-1. Define key terms introduced in this chapter.
10-2. Distinguish between the terms respiration, ventilation, pulmonary ventilation, external respiration, internal respiration, and cellular ventilation.
10-3. Relate the anatomy and physiology of the respiratory system to ventilation and respiration.
10-4. Recognize signs of mild to moderate and severe hypoxia.
10-5. Explain differences between adults and children in the signs of hypoxia.
10-6. Describe the relationship between airway status and mental status.
10-7. Give examples of conditions that can lead to impaired ventilation and respiration.
10-8. Describe how partial or complete obstruction of the airway leads to hypoxia.
10-9. Describe differences between adults and children in the anatomy and physiology of the respiratory system.
10-10. Explain the causes of each of the following abnormal upper airway sounds:
   a. Snoring
   b. Crowing
   c. Gurgling
   d. Stridor
10-11. Demonstrate each of the following procedures necessary for airway assessment and correction:
   a. Opening the mouth of an unresponsive patient
   b. Suctioning the mouth
   c. Head-tilt, chin-lift maneuver
   d. Jaw-thrust maneuver
   e. Insertion of an oropharyngeal airway
   f. Insertion of a nasopharyngeal airway
   g. Positioning a patient for control of the airway
10-12. Describe the performance requirements for fixed suction devices.
10-13. Compare the function of fixed and portable suction devices.
10-14. Compare the use of rigid and soft suction catheters.
10-15. Explain special considerations to be kept in mind when suctioning patients, including signs of hypoxia and patients with copious amounts of vomit that cannot be quickly suctioned.
10-16. Describe the indications, advantages, disadvantages, precautions, uses, and limitations of oropharyngeal and nasopharyngeal airways.
10-17. Distinguish between patients with adequate and inadequate breathing by considering the following:
   a. Minute ventilation
   b. Alveolar ventilation
   c. Inspection of the chest
   d. Patient’s general appearance
   e. Regularity of breathing
   f. Flaring of the nostrils
   g. Patient’s ability to speak
   h. Airflow
   i. Breath sounds
10-18. Identify patients with indications for supplemental oxygen and positive pressure ventilation.
10-19. Describe the physiological differences between spontaneous and positive pressure ventilation.

10-20. Distinguish between adequate and inadequate positive pressure ventilation.

10-21. Demonstrate each of the following procedures for artificial ventilation:
   a. Mouth-to-mouth and mouth-to-mask ventilation
   b. Delivery of positive pressure ventilations with a bag-valve-mask device (one-person and two-person), with a flow-restricted, oxygen-powered ventilation device, and with an automatic transport ventilator

10-22. Differentiate between the duration and volume of ventilation for patients with and without pulses.

10-23. Explain the significance of avoiding gastric inflation when administering positive pressure ventilation.

10-24. Describe indications and methods for administering positive pressure ventilations to a patient who is breathing spontaneously.

10-25. Discuss the indications, contraindications, and methods for administering continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP).

10-26. Discuss the hazards of overventilation.

10-27. Discuss special considerations of airway management and ventilation for the following:
   a. Patients with stomas or tracheostomy tubes
   b. Infants and children
   c. Patients with facial injuries
   d. Patients with foreign body airway obstructions
   e. Patients with dental appliances

10-28. Describe the properties of oxygen.

10-29. Differentiate between the various sizes of oxygen cylinders available.

10-30. Describe the hazards associated with oxygen use and safety precautions to be observed when using oxygen or handling oxygen cylinders.

10-31. Describe the regulation of oxygen pressures, including the uses of high-pressure and therapy regulators.

10-32. Discuss the use of oxygen humidifiers.

10-33. Discuss the administration of oxygen by nonrebreather mask, nasal cannula, simple face mask, partial rebreather mask, Venturi mask, and tracheostomy mask.

**KEY TERMS**

- Adam's apple p. 206
- agonal respirations p. 226
- alveolar ventilation p. 223
- alveoli p. 206
- automatic transport ventilator (ATV) p. 241
- bag-valve-mask (BVM) device p. 236
- bilaterally p. 225
- bilevel positive airway pressure (BiPAP) p. 245
- bradypnea p. 227
- bronchi p. 206
- bronchioles p. 206
- carina p. 206
- chemoreceptors p. 208
- continuous positive airway pressure (CPAP) p. 242
- cricoid cartilage p. 206
- cricoid pressure p. 231
- crossed-fingers technique p. 215
- crowing p. 215
- cyanosis p. 210
- dead air space p. 224
- deoxygenated p. 210
- diaphragm p. 207
- epiglottis p. 205
- esophagus p. 205
- exhalation/expiration p. 207
- external respiration p. 204
- flow-restricted, oxygen-powered ventilation device (FRGPVD) p. 239
- French catheter p. 220
- gastric distention p. 231
- gurgling p. 215
- hard catheter p. 219
- head-tilt, chin-lift maneuver p. 215
- hemoglobin p. 210
- high-pressure regulator p. 250
- hypoperfusion/shock p. 209
- hypoxia p. 209
- inhalation/inspiration p. 207
- intercostal muscles p. 207
- internal respiration p. 204
- jaw-thrust maneuver p. 217
- laryngectomy p. 246
- larynx p. 206
- lower airway p. 206
- minute volume p. 223
- mucous membrane p. 205
- nasal cannula p. 254
- nasopharyngeal airway/nasal airway p. 222
- nasopharynx p. 205
- nonrebreather mask p. 253
- oropharyngeal airway/oral airway p. 221
- oropharynx p. 205
- oxygen humidifier p. 250
- oxygenated p. 210
- oxygenation p. 209
- parietal pleura p. 207
- partial rebreather mask p. 255
- patent airway p. 213
- pharynx p. 205
- pleura p. 207
- pleural space p. 207
- positive pressure ventilation (PPV) p. 229
- pressure regulator p. 249
- residual volume p. 220
- respiration p. 204
- respiratory arrest p. 226
- respiratory distress p. 226
- respiratory failure p. 226
- respiratory rate p. 208
- retractions p. 224
- rigid catheter p. 219
- serous fluid p. 207
- simple face mask p. 255
- snoring p. 214
- soft catheter p. 220
- stoma p. 246
- stridor p. 215
- tachypnea p. 227
- therapy regulator p. 250
- thyroid cartilage p. 206
- tidal volume p. 223
- tonsil tip/tonsil sucker p. 219
- trachea p. 206
- tracheostomy p. 246
- tracheostomy mask p. 255
- tracheostomy tube p. 246
- upper airway p. 205
- ventilation p. 207
- Venturi mask p. 255
- visceral pleura p. 207
INTRODUCTION
Without an open and clear airway, adequate ventilation, or sufficient oxygenation, all other emergency care is futile since the patient will rapidly deteriorate and die. Therefore, these components are part of the primary assessment that is conducted on every patient regardless of the injuries or illness. By understanding the mechanical and physiological processes of respiration and ventilation and the various ways to assist patients with artificial ventilation, you will be able to quickly initiate and maintain an adequate airway and oxygenation in cases of emergency.

RESPIRATION
Respiration is also commonly referred to as ventilation or breathing. These terms are often used synonymously. However, there are true physiological differences between ventilation or breathing and the various types of respiration.

Respiration can be broken down into four distinct components: pulmonary ventilation, external respiration, internal respiration, and cellular respiration and metabolism. Physiologically, the term respiration refers to the gas exchange process that occurs between the alveoli or cells and the capillaries, or to the utilization of glucose and oxygen during normal metabolism within the cells. The following is a brief summary of the components associated with respiration. More detail regarding each component will be provided later in the chapter. You can also review Chapter 8, “Pathophysiology,” for more detail on ventilation and gas exchange.

- **Pulmonary ventilation**, or simply ventilation or breathing, is the mechanical process of moving air in and out of the lungs. It is related to minute ventilation and alveolar ventilation.
- **External respiration** is the gas exchange process that occurs between the alveoli and the surrounding pulmonary capillaries. External respiration, also referred to as alveoli/capillary gas exchange, serves to oxygenate the blood and eliminate carbon dioxide in the lungs.
- **Internal respiration** is the gas exchange process that occurs between the cells and the systemic capillaries. Internal respiration, also known as cell/capillary gas exchange, is responsible for delivering oxygen to the cells and removing carbon dioxide from the cell.
- **Cellular respiration and metabolism**, also known as aerobic metabolism, occurs in the cell. The process breaks down glucose in the presence of oxygen, produces high amounts of energy in the form of ATP, and releases carbon dioxide and water as a by-product.

RESPIRATORY SYSTEM REVIEW
To ensure that you can establish and maintain an open airway and properly ventilate a patient, you should understand some basics of the anatomy and physiology of the respiratory system. What follows is a brief review of that system. You may also wish to review the material on the respiratory system in Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and in Chapter 8, “Pathophysiology.”
Anatomy of the Respiratory System

The respiratory system takes oxygen from air that is breathed in, transports it to the alveoli where the oxygen crosses over into the capillary, and attaches the oxygen to the hemoglobin on the red blood cell or dissolves it in the plasma of the blood. The blood then transports the oxygen to body cells through the arteries and capillaries of the circulatory system. At the capillary/cell interface, the oxygen leaves the blood in the capillary and crosses over into the cell. If the oxygen supply is decreased by an obstructed airway, inadequate breathing, ineffective oxygen exchange in the lungs, or an inadequate delivery system to the cells, the body cells will become hypoxic (low in oxygen) and eventually die.

The respiratory system is also responsible for eliminating carbon dioxide, the major waste product of cellular metabolism, when carbon dioxide crosses out of the cells into the capillaries and is carried by the venous system back to the lungs to be exhaled.

The respiratory system is divided anatomically into the upper airway and the lower airway. Often, conditions are described as affecting the upper or lower airway.

The Upper Airway

The upper airway extends from the nose and mouth to the cricoid cartilage, the most inferior portion of the larynx (Figure 10-1).

Nose and Mouth. Air normally enters the body through the nostrils. It is warmed, moistened, and filtered as it flows over the damp, sticky mucous membrane lining the nose. Air also enters through the mouth; however, there is less filtration and warming by that route than through the nostrils. The tongue is a common cause of airway obstruction in the patient with an altered mental status. This occurs when the muscles controlling the tongue (the submandibular muscles) relax. This causes the tongue to fall back and occlude (block) the airway.

Pharynx. Air entering the body through the mouth and nostrils travels into the pharynx (throat). Air from the nasal passages enters through what is referred to as the nasopharynx. Air entering through the mouth travels through the oropharynx. Both the oropharynx and nasopharynx enter into the pharynx at the back of the throat. The pharynx must be kept clear because obstructions in it can prevent air from traveling into the lower airways, or the substance may be aspirated into the lungs, thus interfering with oxygen and carbon dioxide exchange in the alveoli.

Two passageways are found at the lower end of the pharynx—the trachea and the esophagus. The trachea is the passageway for air traveling into the lungs. Food and water are routed to the esophagus, which leads to the stomach.

Epiglottis. The trachea is protected by a small, leaf-shaped flap of cartilaginous tissue called the epiglottis. This acts as a valve that closes over the opening to the
larynx while food and drink are being swallowed. At other times, the epiglottis is pulled away from the opening to the larynx, which permits breathing. This controlled diversion usually works automatically to keep food and drink out of the trachea and air from going into the esophagus.

At times, the epiglottis may fail to close, and food or liquids can enter the larynx and the upper portion of the trachea, causing a patient to choke. If a patient is unresponsive, the protective reflexes may not work during swallowing, so that foreign objects, blood, secretions, and vomitus can enter the trachea and cause an airway obstruction or lung infection.

When the muscles controlling the tongue relax in a patient with an altered mental status, the muscles controlling the epiglottis also relax and may cause the epiglottis to fall over the opening of the larynx (glottic opening). This will block the only opening to the trachea and cause an airway obstruction at the level of the larynx that cannot be directly seen by the EMT. The best method to relieve this type of obstruction is to perform a head-tilt, chin-lift maneuver or jaw-thrust maneuver (described later), which will pull the epiglottis up away from the opening of the larynx.

**Larynx.** Just superior to (above) the trachea and just inferior to (below) the epiglottis is the **larynx**, or voice box, which contains the vocal cords (Figure 10-2 ■). The vocal cords are thin muscles that produce speech and also protect the lower airway. The anterior portion of the larynx is composed of the large bulky **thyroid cartilage**, commonly known as the Adam’s apple, which can be felt at the front of the throat. The **cricoid cartilage**, which forms the most inferior portion of the larynx and is the only completely circular cartilaginous ring of the upper airway, is found at the lower portion of the larynx just below the thyroid cartilage. Pressure applied to the cricoid ring, a technique that will be discussed later, is often used in airway management to help prevent air from filling the stomach and to help prevent regurgitation of stomach contents. The larynx is a common site of airway obstruction in adults, infants, and children.

**The Lower Airway**

The **lower airway** extends from the cricoid cartilage at the lower edge of the larynx to the alveoli of the lungs (Figure 10-3 ■).

**Trachea.** The **trachea**, commonly known as the windpipe, is the passageway for air entering the lungs. It extends from the larynx to the **carina**, the point at which the trachea splits into the right and left mainstem bronchi. The anterior portion of the trachea is composed of strong C-shaped cartilaginous rings that provide support and structure. The posterior wall of the trachea is made up of muscle and therefore is not a rigid structure.

**Bronchi and Bronchioles.** The right and left mainstem **bronchi**, which are the two major branches of the trachea, extend from the carina into the lungs, where they continue to divide into smaller sections or branches known as **bronchioles**. The bronchi are larger airways and contain cartilage. The bronchioles, which become increasingly smaller as they continue to branch, are lined with smooth muscle and mucous membranes. The smooth muscle can contract and the mucous lining can become inflamed and swollen, severely narrowing the diameter of the bronchiole and causing lower airway obstruction, as is seen in asthma. This narrowing causes an increase in airway resistance inside the bronchiole, which makes it more difficult for the patient to move air into and out of the alveoli and the lower airway passages. An increase in airway resistance causes the patient to work harder to breathe, which may lead to fatigue and failure of the respiratory muscles. This would produce ineffective and inadequate ventilation and oxygenation, leading to cell hypoxia.

**Lungs.** The bronchioles terminate in millions of tiny air sacs in the lungs. These are called the **alveoli**. Each air sac is wrapped in a web of thin-walled capillaries.
referred to as the pulmonary capillaries. This is the site for gas exchange between the alveoli and the blood in the capillaries.

The lungs are made of elastic tissue. This elastic tissue causes the lungs to react like a rubber band; thus, the lungs' natural tendency is to recoil and collapse. The lungs are surrounded by two layers of connective tissue called the pleura. The visceral pleura is the innermost covering of the lung. The parietal pleura is a thicker, more elastic layer that adheres to the inner portion of the chest wall. Between the two layers is the pleural space, a small space that is at negative pressure. The pleural space contains a small amount of serous fluid that acts as a lubricant to reduce friction when the layers of the pleura rub against each other during breathing.

Since the lung tissue wants to recoil and collapse, because of its elastic properties, it is always tugging inward toward the midline of the body. However, the parietal pleura, connected to the chest wall, retains the lungs' structure and prevents them from collapsing. The serous fluid between the attached parietal pleura and the visceral pleura, which is always tugging inward, creates a “water glass” effect. If a water glass is placed open end down on a flat surface covered with water, then pulled straight upward, a vacuum is created between the flat surface and the glass. The water creates a seal. If the seal is broken, air is sucked inward and allows the glass to be moved off the flat surface. To apply this principle, think of the patient who has an open wound to the chest with a tear in the parietal or visceral pleura. The visceral pleural pull is continuously creating a vacuum, so air from outside the chest gets sucked into the pleural space through the hole in the pleura. Since the lung wants to recoil, it continues to pull inward toward the midline, collapsing the lung as air fills the pleural space. The lung continues to collapse as more air enters the pleural space. This is frequently seen in blunt and penetrating injuries to the chest and can lead to severe respiratory distress and inadequate gas exchange and oxygenation of the cells.

**Diaphragm.** The diaphragm is a muscle that separates the chest cavity from the abdominal cavity. It is the major muscle used in breathing. It is responsible for approximately 60–70 percent of the effort of ventilation. If contraction of the diaphragm is ineffective because of trauma or illness, the patient may show signs of significant respiratory distress from inadequate breathing.

**Mechanics of Ventilation (Pulmonary Ventilation) Review**

The passage of air into and out of the lungs is called ventilation. It is also often referred to as breathing, pulmonary ventilation, or respiration. Ventilation is a mechanical process that creates pressure changes in the lungs to draw air in and force air out. **Inhalation** or **inspiration** is the process of breathing air in, and **exhalation** or **expiration** is the process of breathing air out (Figure 10-4 ■).

**Inhalation.** During inhalation, the diaphragm and the external intercostal muscles, or muscles between the ribs, contract. The diaphragm moves slightly downward and flares the lower portion of the rib cage outward. The external intercostal muscles pull the ribs and sternum upward and outward. These actions increase the size of the chest cavity, creating negative pressure inside the chest cavity. This draws air by way of the nose, mouth, trachea, and bronchi into the lungs until the pressure inside the lungs is equal to the atmospheric pressure outside the body. Inhalation is an active process because it requires energy to contract the muscles.
Exhalation. During exhalation, the diaphragm and external intercostal muscles relax, moving the diaphragm upward and the ribs and sternum downward and inward back to their normal resting positions. The size of the chest cavity is reduced, the elastic lung tissue recoils to its normal position, and the pressure in the chest cavity becomes positive. This forces a volume of air out of the lungs. Because this process involves relaxation of muscles and little energy is expended, it is considered to be passive.

In some respiratory diseases affecting the lower airway, such as asthma, the patient has a difficult time moving air out of the lungs because of an increased resistance in the airways or diseased lung tissue. There is a loss of the elastic recoil of the chest wall and lungs because air is trapped in the alveoli. Therefore, the patient has to contract muscles, not only to draw air into the lungs but also to force air out of the lungs. As a consequence, both inhalation and exhalation become active, requiring energy. Such patients have a tendency to become exhausted very quickly because of the amount of energy it takes to breathe. They are prone to a rapid deterioration from fatigue of the respiratory muscles.

Control of Respiration. Unlike the heart, which can generate contractions from within the heart’s own muscle and conductive system, the respiratory organs do not have the ability to control their function from within the respiratory system. Respirations are controlled by the nervous system in a variety of ways. The dorsal respiratory group (DRG), ventral respiratory group (VRG), and pontine respiratory center (pneumotaxic center) in the brainstem are respiratory rhythm centers that control the impulses being sent to the respiratory muscles. The chemoreceptors continuously monitor levels of oxygen, carbon dioxide, and pH (hydrogen ion concentration) in the arterial blood and stimulate an increase or decrease in impulses from the respiratory rhythm centers to control the rate and depth of ventilation.

PATHOPHYSIOLOGY PEARLS

The central chemoreceptors located in the medulla are most sensitive to changes in the blood pH and carbon dioxide, whereas the peripheral chemoreceptors located in the carotid arteries and aortic arch are more sensitive to changes in arterial oxygen.

The respiratory system responds primarily to changes in the carbon dioxide levels. If the carbon dioxide level in arterial blood increases, the chemoreceptors sense the increase and the brainstem sends impulses to the respiratory muscles to increase the rate and depth of respiration. The increase in respirations results in the increased elimination of carbon dioxide. Thus healthy people breathe on a hypercarbic (high carbon dioxide) drive. When the carbon dioxide level decreases in the blood, the chemoreceptors sense this and send signals to the respiratory muscles to slow down the respiratory rate and depth and the respirations return to normal. Oxygen is much less of a stimulus for breathing in healthy people.

In patients with a category of conditions known as chronic obstructive pulmonary disease (COPD), which includes emphysema and chronic bronchitis, the carbon dioxide level in arterial blood is typically chronically elevated as a result of the disease process. Because of the constant high carbon dioxide levels, the chemoreceptors become relatively insensitive to changes in carbon dioxide. Instead, the chemoreceptors of COPD patients tend to rely on oxygen levels in the blood to regulate their breathing. These patients breathe on a
hypoxic (low oxygen) drive, since they breathe to increase their oxygen levels and not to reduce their carbon dioxide levels. This could affect your management of the patient when considering oxygen therapy.

In some cases, if oxygen is provided at high concentrations to a patient with COPD over a long period of time, the oxygen levels in the arterial blood will rise beyond a normal level for that patient. The chemoreceptors will sense this rise and may send signals to the respiratory muscles to slow down or even stop respirations, because the oxygen levels are more than adequate in the blood and no more oxygen is needed at that time. The result can be respiratory failure or respiratory arrest, although this rarely happens in the short period of time when a patient is receiving prehospital care. Even though this could be a complication in the COPD patient, oxygen should never be withheld from a patient if he needs it, whether he has COPD or not. If it should occur, ventilate the patient artificially, just as with any patient who suffers respiratory failure or arrest.

Respiratory Physiology Review

Oxygenation is the process by which the blood and the cells become saturated with oxygen. This happens as a result of internal respiration and external respiration, the processes in which fresh oxygen replaces waste carbon dioxide, a gas exchange that takes place between the alveoli and the capillaries in the lungs, and also between the capillaries and the cells throughout the body. As noted earlier, ventilation is the mechanical process of moving air in and out of the lungs, and respiration is the physiological process of gas exchange.

Hypoxemia

Hypoxemia is a low oxygen content in arterial blood. This typically occurs from a ventilation-perfusion mismatch. A ventilation-perfusion mismatch occurs when there is a lack of available oxygenated air in the alveoli even though perfusion (blood flow) to the alveoli is adequate, or when the alveoli are adequately oxygenated but perfusion to the alveoli is poor, or when there is a combination of both poor ventilation and poor perfusion in the alveolar-capillary structures. Other possible causes of hypoxemia include inadequate ventilatory drive, anemia, and carbon monoxide poisoning.

Hypoxia

Hypoxia refers to an inadequacy in the amount of oxygen being delivered to the cells. It is a more general term than hypoxemia which, as just described, refers only to low oxygen content in the arterial blood. Hypoxia can result from a large number of causes, including an occluded airway, inadequate breathing, inadequate delivery of oxygen to the cells by the blood (hypoperfusion or shock), inhalation of toxic gases (e.g., carbon monoxide), lung and airway diseases (e.g., asthma, emphysema), drug overdose that suppresses the respiratory center in the brain (e.g., morphine, heroin, and other narcotics), stroke, injury to the chest or respiratory structures, and head injury. There are many more conditions or injuries that may create a blockage to the airway or produce inadequate breathing by depressing the respiratory centers in the brain, interfering with gas exchange at the level of the alveoli, or restricting the movement of the chest wall.

The signs of hypoxia may be subtle. It is extremely important to continuously assess the patient for hypoxia and to recognize its subtle signs and symptoms. The following are signs of hypoxia:

**Signs of Mild to Moderate Hypoxia**
- Tachypnea (increased respiratory rate)
- Dyspnea (shortness of breath)
- Pale, cool, clammy skin (early)
- Tachycardia (increase in heart rate)
- Elevation in blood pressure
- Restlessness and agitation (from hypoxic brain cells)
- Disorientation and confusion (from high carbon dioxide levels in the blood)
- Headache

**Signs of Severe Hypoxia**
- Tachypnea
- Dyspnea
- Cyanosis (bluish gray color to skin, mucous membranes, and nail beds)
- Tachycardia that may lead to dysrhythmias (irregular heart rhythms) and eventually bradycardia (slow heart rate)
- Severe confusion
- Loss of coordination
- Sleepy appearance (from high carbon dioxide levels in the brain)
- Head bobbing (head bobs upward with inhalation and downward with exhalation, as if falling asleep while sitting upright) with droopy eyelids (from high carbon dioxide levels in the brain)
- Slow reaction time
- Altered mental status
- Seizure

In a newborn, bradycardia (slow heart rate) may be an early sign of hypoxia. Infants and young children normally have higher heart rates than adults. As an example, a heart rate of 80 bpm, which would be normal in an adult, may be an indication of hypoxia in a week-old infant where a heart rate of 120–150 bpm would be normal. It is important in the assessment of newborns to suspect hypoxia as a cause of a slower-than-expected heart rate, since this is a primary cause of bradycardia in this group. In infants, children, and adults, bradycardia is a sign of severe hypoxia and impending respiratory and cardiac arrest.
It is important to assess for the early signs of hypoxia. The skin will become pale, cool, and clammy early. You may also find tachypnea (rapid breathing) and tachycardia (rapid heartbeat). Early changes in the mental status may occur in the form of restlessness or agitation and confusion. Hypoxia causes restlessness and agitation in the patient, whereas the buildup of carbon dioxide in the blood will cause the patient to become confused. These most often occur together; therefore, your patient will likely appear both agitated and confused. If a patient presents with agitation and confusion, it is extremely important that you suspect and assess for evidence of inadequate ventilation and oxygenation in the patient.

**ASSESSMENT TIPS**

An early sign of hypoxia is an alteration in the patient’s mental status.

**Cyanosis,** a bluish gray color, is a late sign of hypoxia and may be found in and around several areas of the body, including the lips, mouth, nose, fingernail beds, conjunctiva (the normally red area between the bottom eyelid and the eyeball), and oral mucosa (between the lips and gums, and the tongue) (Figure 10-5). In a dark-skinned patient, the fingernail beds may appear more pale than cyanotic. In dark-skinned patients, be sure to check the oral mucosa or conjunctiva for cyanosis. In summary, it is important in your assessment of the patient to look at these various areas to determine if cyanosis exists.

**PATHOPHYSIOLOGY PEARLS**

An early sign of hypoxia is pale, cool, and clammy skin. This set of skin signs is caused by the effect of hypoxia on the vasomotor center in the medulla oblongata of the brain. The vasomotor center controls the size of the arteries and arterioles, thereby altering the blood pressure. Vasconstriction increases the blood pressure. As the vasomotor center senses hypoxia, its response is to increase the blood pressure by triggering the sympathetic nervous system to vasconstrict arteries and arterioles to provide more oxygenated blood to the brain. The vasconstriction shunts blood away from the peripheral arteries and arterioles and produces pale, cool skin seen early in hypoxia. Stimulation of the sweat glands by the sympathetic nervous system produces the clammy skin.

**PATHOPHYSIOLOGY PEARLS**

Cyanosis occurs when adequate amounts of oxygen are no longer attached to the hemoglobin molecules. However, hemoglobin must be present in the blood to change its color. Thus, a patient with severe bleeding who is hypoxic may not exhibit extreme cyanosis, since there may not be large enough amounts of hemoglobin in the blood to produce the bluish color of cyanosis.

If the patient is displaying any signs of hypoxia, immediately assess the airway and adequacy of breathing. If the airway is open and the patient is breathing adequately (adequate rate and volume), apply a nonrebreather mask and administer a high concentration of oxygen. If the patient’s airway is not open, immediately open it and assess the breathing status. If the breathing status is inadequate (either an inadequate rate or an inadequate volume), immediately begin positive pressure ventilation. These oxygen administration and ventilation techniques will be discussed in greater detail later in the chapter.

**Alveolar/Capillary Exchange (External Respiration)**

Oxygen-rich air enters the alveoli during each inspiration. Surrounding the alveoli are capillaries that deliver blood to the alveoli. The blood moving into the capillaries is deoxygenated, that is, with low oxygen concentration, but is high in carbon dioxide. The alveoli contain an enriched supply of oxygen and very little carbon dioxide. Because both gases move from areas of high concentration to areas of low concentration, the oxygen diffuses (moves) from the alveoli into the capillaries, and the carbon dioxide diffuses (moves) from the capillaries into the alveoli (Figure 10-6a). From this point, the blood in the capillaries is oxygenated, that is, with high oxygen concentration and low carbon dioxide. Hemoglobin, found on the surface of red blood cells, is responsible for picking up the majority of oxygen in the blood, approximately 97 percent, and carrying it through the arterial system to the capillaries throughout the body. The carbon dioxide is exhaled from the alveoli and
out of the lungs. Oxygenation is required; however, it does not ensure adequate internal respiration and aerobic metabolism. Although the blood may be saturated with oxygen from the alveolar capillaries, a disturbance in the delivery or the off-loading of the oxygen from the hemoglobin would result in a decrease in internal respiration and, consequently, in cellular hypoxia.

**Capillary/Cellular Exchange (Internal Respiration)**

The blood entering the capillaries surrounding the body’s cells has a high oxygen content and a low carbon dioxide content. The cells have high levels of carbon dioxide and low levels of oxygen from normal metabolism. Again, because oxygen and carbon dioxide move from areas of high concentration to those of low concentration, the oxygen moves out of the capillaries and into the cells and the carbon dioxide moves out of the cells and into the capillaries (Figure 10-6b). The blood, now low in oxygen and high in carbon dioxide, moves out of the capillaries and into the venous system where it is transported back to the lungs for gas exchange.

**Pathophysiology of Pulmonary Ventilation and External and Internal Respiration**

A disturbance in pulmonary ventilation, oxygenation, external respiration, internal respiration, or circulation can lead to cellular hypoxia and the conversion from aerobic to anaerobic metabolism. Anaerobic metabolism is associated with insufficient energy production and the buildup of lactic acid, which can affect cellular function and integrity. A severe alteration in perfusion can also cause a decrease in glucose delivery to the cells. Without a fuel source, the cells will fail to produce energy and will eventually die.

A disruption in the mechanical process of pulmonary ventilation may occur from one of the following:

- Interruption of the nervous system’s control and stimulation of the diaphragm or of the external intercostal muscles may result from a brain injury, from drugs that depress the central nervous system, or from neuromuscular diseases such as muscular dystrophy.
- Structural damage to the thorax may interfere with the bellows action of the chest. This will impede the ability of the thorax to generate pressure changes necessary
to draw air into the lungs for inhalation and to allow airflow out of the lungs during exhalation. Pain associated with chest injury, flail chest (two or more ribs fractured in two or more places), rupture or injury to the diaphragm, or compression of the chest wall can reduce the effective bellows action of the chest.

- Increased airway resistance will reduce airflow through the respiratory tract and reduce the amount of air in the alveoli. This will make less oxygen available for gas exchange. An increase in airway resistance may occur from bronchoconstriction or from inflammation inside the vessel.

- Disruption of airway patency can occur from swelling caused by infection, allergic reaction, or burns; from trauma; from foreign body obstruction; or from loss of muscle tone associated with an altered mental status or unresponsiveness. Reduction or loss of airway patency will reduce the tidal volume, minute ventilation, alveolar ventilation, and volume of gas in the lungs for gas exchange.

A reduction in the oxygen content of the ambient atmosphere will decrease the available oxygen for gas exchange in the alveoli and at the cells, leading to cellular hypoxia. The oxygen content may be reduced by toxic gases, an enclosed space without adequate ventilation, or a high altitude.

Certain conditions or diseases can obstruct or disrupt the exchange of gas between the alveoli and capillaries. Pneumonia, pulmonary edema, and drowning cause fluid to fill the alveoli, collapse the alveoli, or increase the space between the alveoli and the capillaries, all of which hinder the movement of oxygen from the alveoli into the capillaries and the movement of carbon dioxide from the capillaries into the alveoli. Other diseases, such as emphysema, distort the structure of the alveoli and change the surface area for effective gas exchange. Some toxic gases, such as cyanide and carbon monoxide, interfere with oxygen use by the cell once it has been delivered. These conditions lead to a disruption in both internal and external respiration.

Another cause of cellular hypoxia is poor perfusion or a decreased ability of the blood to carry oxygen. Conditions that obstruct forward movement of blood flow, such as a pulmonary embolism, tension pneumothorax, heart failure, and cardiac tamponade, reduce the delivery of oxygenated blood to the cells. They also reduce perfusion in the pulmonary capillaries, making less blood available to pick up oxygen. Other conditions such as anemia or hypovolemia reduce the concentration of red blood cells and hemoglobin in the blood, making oxygen transport less effective.

**Airway Anatomy in Infants and Children**

The causes of airway obstruction and inadequate breathing in infants and children are usually similar to those in adults. However, there are several anatomical features in infants and children that may cause them to deteriorate more rapidly than adults (Figure 10-7 ■).

**Mouth and Nose**

The noses and mouths of infants and children are smaller than those of adults. Thus, they are more easily obstructed by foreign bodies, swelling, blood, mucus, and secretions. Infants are obligate nose breathers, meaning that they want to breathe through the nose and not the mouth; thus it is especially important to keep the nose clear of obstructions.

![Comparison of airways of adult and infant or child](image-url)
**Pharynx**

Because the tongue of an infant or a child is relatively large in proportion to the size of the mouth, it takes up more room. Therefore, an infant or a child is more prone to airway obstruction by posterior displacement of the tongue at the level of the pharynx. Also, the epiglottis is more U-shaped and can protrude into the pharynx, contributing to obstruction.

**Trachea and Lower Airway**

The trachea and lower airway passages of infants and children are narrower, softer, and more flexible than those of adults. Thus, airway obstructions occur more easily from mucus, pus, blood, secretions, swelling (edema), constriction, and kinking of the trachea with flexion or extension. Very small reductions in the diameter of the lower airway result in significant airway obstruction and high resistance to airflow, reducing effective breathing and oxygenation. Because the young child’s head is larger in proportion to his body, the head tends to tilt forward, flexing the neck and potentially collapsing the trachea, when the child is placed on his back for oxygenation or ventilation. For a child less than 2 years of age, padding under the child’s shoulders is necessary to keep the airway aligned and the trachea open (Figure 10-8 ■). For a child greater than 2 years of age, place padding under the occiput. In both cases, proper positioning places the external ear canal anterior to the shoulder.

**Cricoid Cartilage**

The cricoid cartilage, like other cartilage in infants and children, is less developed and less rigid. Also, in infants and children less than 10 years of age, the cricoid cartilage is typically the narrowest portion of the upper airway.

**Chest Wall and Diaphragm**

The chest wall in an infant or a child is softer and more pliable than in an adult. This leads to a much greater compliance (elasticity, response to pressure) or movement during ventilation. Infants and children rely more on the diaphragm for breathing. The intercostal muscles contribute less in normal breathing and act more like accessory muscles. That is why retractions are seen more prominently in infants and young children as compared to adults. When you perform artificial ventilation on an infant or child, the chest should expand and rise easily. If the chest does not rise, you should assume that the airway is not adequately open or is occluded by an obstruction, or the ventilation volume is inadequate. Because the chest expands so easily, it is much easier for the EMT to overinflate the lungs and cause possible lung injury.

**Oxygen Reserves**

Infants and children are smaller and have more limited oxygen reserves than adults. Therefore, they have less oxygen in the lungs available during periods of inadequate breathing or apnea (complete cessation of breathing). Also, they have twice the metabolic rate of adults, causing them to use oxygen at a much faster rate. Their smaller reserve of oxygen and greater metabolic rate will cause infants and children to become hypoxic more rapidly than adult patients. Hypoxia is the most common cause of cardiac arrest in children.

**AIRWAY ASSESSMENT**

An open airway is necessary for adequate breathing and oxygenation. Therefore, assessment of the airway is the first component in the primary assessment of the patient. An open airway is commonly referred to as a patent airway.

**Airway Functions and Considerations**

The following are general functions and considerations regarding the airway:

- The airway and respiratory tract is the conduit that allows air to move from the atmosphere and into the alveoli for gas exchange.
• No matter what the patient’s condition, the airway must remain patent at all times.
• Any obstruction (food, blood, swelling, vomit) of the airway will result in less air movement, which will lead to some degree of poor gas exchange and potential hypoxia.
• The degree of the obstruction will directly affect the amount of air available for gas exchange. The tongue may create only a partial airway obstruction, whereas a piece of food may completely stop airflow.

The mental status of a patient typically correlates well with the status of his airway. An alert, responsive patient who is talking to you in a normal voice has an open airway. It takes an open and clear airway, along with adequate breathing, to enable a patient to communicate easily. Table 10-1 lists signs of an open airway.

A patient who has an altered mental status or is completely unresponsive cannot adequately protect his own airway and has the potential for airway occlusion or obstruction. The tongue relaxes and falls back, blocking the pharynx. The epiglottis can also relax and obstruct the airway at the level of the larynx. The patient may lose his gag or cough reflex, making him susceptible to aspiration. Efforts by the patient to breathe will create a negative pressure; this may draw the tongue, epiglottis, or both into the airway to block airflow into the trachea and lungs. The airway may also be obstructed from injuries such as burns and soft tissue trauma to the face and upper airway (Figure 10-9 ■).

**TABLE 10-1 Signs of an Open Airway**

- Air can be felt and heard moving in and out of the mouth and nose.
- The patient is speaking in full sentences or with little difficulty.
- The sound of the voice is normal for the patient.

**ASSESSMENT TIPS**

A patient who has an altered mental status but continues to maintain a gag or cough reflex could still aspirate blood, secretions, vomitus, or other substances.

**Abnormal Upper Airway Sounds**

When assessing the airway in the patient with a severely altered mental status, it is necessary to open the mouth manually, perform a manual airway maneuver, inspect inside the mouth, and listen for any abnormal sounds. The following are sounds that may indicate airway obstruction:

- **Snoring** (sonorous sounds) occurs when the upper airway is partially obstructed by the tongue or by relaxed tissues in the pharynx. The snoring and obstruction can be corrected by performing a head-tilt, chin-lift maneuver. This lifts the base of the tongue.

![Figure 10-9](image-url) The airway can be blocked by injuries such as (a) burns or (b) soft tissue trauma.
from the back of the pharynx (throat). In a patient with a suspected spinal injury, a jaw-thrust maneuver should be used.

- **Crowing** is a sound like a crow cawing that occurs when the muscles around the larynx spasm and narrow the opening into the trachea. Air rushing through the restricted passage causes the sound.

- **Gurgling**, a sound like gargling, usually indicates the presence of blood, vomitus, secretions, or other liquid in the airway. Immediately suction the substance from the airway.

- **Stridor** is a harsh, high-pitched sound heard during inspiration. It is characteristic of a significant upper airway obstruction from swelling in the larynx. Stridor may also be heard if a mechanical obstruction by food or other objects is present.

Signs of a blocked or inadequate airway are found in Table 10-2.

### Opening the Mouth

It is necessary to open the mouth of an unresponsive patient or a patient with an altered mental status to adequately assess the airway. This is done by using the **crossed-fingers technique** (Figure 10-10):  
1. Kneel above and behind the patient.  
2. Cross the thumb and forefinger of one hand.  
3. Place the thumb on the patient’s lower incisors and your forefinger on the upper incisors.  
4. Use a scissors motion or finger-snapping motion to open the mouth.

Inspect inside the mouth for vomitus, blood, secretions, broken teeth, or foreign bodies that can obstruct the airway. Suction any foreign substance from the mouth. If suction equipment is not immediately available, turn the patient on his side (only perform this move if no spinal injury is suspected) and wipe the fluids away with your index and middle fingers wrapped in a cloth or gauze pad. If you can see foreign objects, such as food, broken teeth, or dentures, sweep the mouth with your index finger and remove them. Do this quickly. Be extremely cautious because the patient could bite down on your fingers, gag, or vomit.

### Opening the Airway

Before a patient who is breathing inadequately can receive positive pressure ventilation, or breathing assistance in which air is forced into his lungs, he must have an open airway. The following are techniques that are used to open and maintain a patent airway.

- **Manual airway maneuvers**
  1. Head-tilt, chin-lift maneuver
  2. Jaw-thrust maneuver
- **Suction**
- **Mechanical airways**
  1. Oropharyngeal airway (oral airway)
  2. Nasopharyngeal airway (nasal airway)

If obvious blood, vomitus, secretions, or other substances are found in the mouth when you come in contact with the patient, immediately suction the substance from the oropharynx and nasopharynx prior to initiating a manual airway maneuver. It may be necessary to turn the patient on his side to remove heavy vomitus or large amounts of blood, fluid, or other secretions. Turning the patient on his side can only be done when you do not suspect a spine injury. Open the airway manually by using either the head-tilt, chin-lift maneuver or the jaw-thrust maneuver. Generally, the head-tilt, chin-lift maneuver is used. However, if you suspect that a patient may have suffered a spinal injury, then use the jaw-thrust maneuver in conjunction with manual in-line spinal stabilization.

### Head-Tilt, Chin-Lift Maneuver

The **head-tilt, chin-lift maneuver** should be used for opening the airway in a patient who has no suspected spinal injury. This is only a temporary maneuver and must be supplemented with a mechanical airway device if the airway can’t be adequately maintained with the head-tilt, chin-lift maneuver alone, or if ventilation of...
the patient is necessary. The head-tilt, chin-lift maneuver is illustrated in Figures 10-11a to 10-11d and summarized here:

1. Place one hand on the patient’s forehead, and apply firm, backward pressure with the palm of the hand to tilt the head back. Place the tips of the fingers of the other hand underneath the bony part of the lower jaw.

2. With the head tilted backward, lift the jaw upward to bring the patient’s chin forward. Do not compress the soft tissues underneath the chin; they might obstruct the airway.

3. Continue to press the other hand on the patient’s forehead to keep the head tilted backward.

4. Lift the chin and jaw so that the teeth are brought nearly together. (If necessary, you can use your thumb to depress or retract the lower lip; this will keep the patient’s mouth slightly open.)

5. If the patient has loose dentures, hold them in position, making obstruction by the lips less likely. A seal is easier to form when the dentures are in place. If the dentures cannot be managed, remove them.

Examples of patients who require a head-tilt, chin-lift maneuver are:

- An unresponsive patient with no suspicion of spinal trauma
- A patient with cardiac arrest not due to trauma
- An apneic (not breathing) patient with no signs of trauma

Head-Tilt, Chin-Lift Maneuver in Infants and Children

The preferred method of opening the airway in infants and children without suspected spinal injury is the head-tilt, chin-lift maneuver (Figure 10-12).

The hand positions and procedures for performing the head-tilt, chin-lift maneuver with infants and children are the same as with adults except for a variation in head positioning. With an infant, the head should be tilted back gently into a “sniffing” or neutral position. As noted earlier, because of the large size of the head, it may be necessary to place a pad behind the shoulders to keep the airway open, until about the age of 4 years.
Because of the underdeveloped airway structures in the infant, care must be taken not to overextend the infant’s head; this could lead to an obstruction of the trachea. With a child, the head is tilted only slightly back from the neutral position. Only the index finger of one hand lifts the chin and jaw. Be careful not to press on the soft tissue beneath the chin, which may cause an airway obstruction.

**Jaw-Thrust Maneuver**

If a spinal injury is suspected, the patient’s head and neck must be brought into and maintained in a neutral, in-line position. This means that the head is not turned to the side, tilted forward (flexed), or tilted backward (extended). The *jaw-thrust maneuver* is used to open the airway in such a patient because the head and neck are not tilted back during this maneuver. The jaw (mandible) is displaced forward by the EMT’s fingers; this causes the patient’s tongue to be pulled forward, away from the back of the airway. If the head-tilt, chin-lift maneuver is unsuccessful in opening the airway of the non-spine-injured patient, perform the jaw-thrust maneuver. This is only a temporary maneuver and must be supplemented with a mechanical airway device if the airway can’t be adequately maintained with the jaw thrust alone, or if continued ventilation of the patient is necessary. The procedure for the jaw thrust is illustrated in Figure 10-13. It involves the following steps:

1. Kneel at the top of the patient’s head. Place your elbows on the surface on which the patient is lying, putting your hands at the side of the patient’s head.
2. Grasp the angles of the patient’s lower jaw on both sides. Move the jaw forward with both hands. This will move the tongue forward, away from the airway. If no spinal injury is suspected, the head could be tilted backward.
3. Retract the lower lip with your thumb if the lips close.

If the jaw thrust does not establish an open airway, reposition the jaw. If repositioning is not effective, insert an oral or nasal airway adjunct, as explained later in this chapter. The EMT holding the in-line stabilization can also establish and maintain the jaw thrust. The jaw thrust would be used in unresponsive patients with suspected spinal injury or trauma patients in need of a manual maneuver to open the airway.
Jaw-Thrust Maneuver in Infants and Children

Follow the basic procedure just described for adults when performing the jaw-thrust maneuver in infants and children (Figure 10-14). Place two or three fingers of each hand at the angle of the jaw to lift it up and forward while the other fingers guide the movement. Insert an airway adjunct if the jaw thrust does not open the airway.

Positioning the Patient for Airway Control

If the patient has an altered mental status and may be at risk of aspirating blood, secretions, or vomitus, place the patient in a modified lateral (recovery) position (Figure 10-15). This is also known as the coma or recovery position. Place the patient’s arm that is closest to you flat on the ground at a right angle to the body. Log roll the patient onto his side. Place the hand of the opposite arm (now on top) under his lateral face and cheek. Bend the leg at the hip and knee to stabilize the body in this position. This positioning is only used in patients who do not have a suspected spinal injury and in patients who are not in need of positive pressure ventilation. If a spinal injury is suspected, the patient must remain supine with manual in-line stabilization maintained until the patient is completely immobilized to a backboard. At that point, the entire board-with-patient can be log rolled to assist with the drainage of secretions, blood, and vomitus. In order to ventilate a patient effectively when no advanced airway device is in place, the patient must be in a supine position.

When using this position, the body should be as lateral as possible. The head needs to be placed so that the secretions, blood, or vomitus will flow out of the mouth freely. Any pressure on the chest that might interfere with breathing must be avoided. A prone position (face down) will drain secretions; however, it may reduce effectiveness of ventilation by pushing the abdominal contents upward toward the head and against the diaphragm, limiting its movement. This may lead to inadequate ventilation and severe hypoxia. Therefore, never use a prone position. If it is necessary to leave the patient in the modified lateral position for greater than 30 minutes, turn him to the other side after 30 minutes. If there are any signs of impaired blood flow to the bottom extremities, turn the patient to the opposite side.

Suctioning

It is necessary to remove any blood, vomitus, secretions, and any other liquids, food particles, or objects from the mouth and airway since they can cause obstruction. Such substances are best removed through the use of suction devices. If a gurgling sound is heard when you are assessing the airway or during artificial ventilation, immediately apply suction to remove the liquid from the airway. Failure to do so will force the liquid substance farther down the airway and possibly into the lungs.

Some suction equipment is not very effective in removing thick vomitus or solid objects, such as teeth, foreign bodies, or food, from the airway. In such situations, it may be necessary to place the patient on his side and perform a finger sweep to remove the material.

Standard Precautions During Suctioning

Because suctioning involves removal of body fluids and the potential for coughing and spatters, you must take appropriate Standard Precautions. Protective eyewear, a mask, and gloves should be used. If a patient is known to have tuberculosis or displays signs and symptoms consistent with tuberculosis, an N-95 or high-efficiency particulate air (HEPA) respirator should be worn at all times in addition to eyewear and gloves.

Suction Equipment

Suction equipment includes the device that creates the suction as well as the catheters that are inserted in the airway. Various types of fixed and portable suction devices and catheters are available.
Mounted Suction Devices. Fixed or installed units should be part of the required on-board ambulance equipment (Figure 10-16). They should be powerful enough to provide an airflow of >40 lpm at the end of the delivery tube and create a vacuum of more than −300 mmHg on the gauge when the tubing is clamped or kinked. The device should be adjustable to allow for a reduced vacuum when suctioning infants and children. Such fixed systems are powered by an electric vacuum pump or by the vacuum produced by the ambulance engine manifold.

Portable Suction Devices. A portable unit must produce a vacuum adequate to suction substances from the pharynx. A pressure of −80 to −120 mmHg is generally necessary to provide adequate suction. The device should be capable of generating −300 mmHg of pressure when the suction hose is clamped. Portable suction units can be electric-, oxygen-, air-, or hand-powered (Figure 10-17). These suction units should be inspected before each shift or on a regular basis.

Electric suction devices must have fully charged batteries to function effectively. A low battery charge will reduce the effective vacuum and the length of time the unit can be used. Some units allow for constant charging so that the batteries are always fully charged when needed.

Oxygen-powered devices function only as long as a source of oxygen is available. Once the oxygen source has run out, the vacuum is lost and suction becomes ineffective.

Hand-powered suction devices (Figure 10-18) do not require any energy source other than an EMT to create the vacuum. Therefore, these devices lack some typical problems associated with electric- or oxygen-powered devices. Also, hand-powered units can more effectively suction heavier substances, such as thick vomitus.

Any type of portable suction device must have the following:

- Wide-bore, thick-walled, nonkinking tubing that fits standard rigid or soft suction catheters
- An unbreakable collection bottle or container (preferably disposable) and a supply of water for rinsing and clearing the tubes and catheters
- Enough vacuum pressure and flow to suction substances from the pharynx effectively

Suction Catheters. Suction catheters must be disposable and capable of being connected to the suction unit’s tubing. Two different types of suction catheters are available:

- **Hard or rigid catheter**—This type of catheter is a rigid plastic tube. It is called a Yankauer catheter and is commonly referred to as a **“tonsil tip”** or **“tonsil sucker.”** It is used to suction the mouth and oropharynx of an unresponsive patient. It is more effective for particulate matter than a soft catheter. The catheter should be inserted only as far as you can see, typically not farther than the base of the tongue. The tip of the suction catheter may stimulate a gag reflex and cause vomiting if it touches the back of the oropharynx. Also, the vagus nerve may be stimulated, causing the patient to become bradycardic. If you are using a **hard catheter** on an infant or child, be careful when applying suction, because doing so might cause soft tissue trauma and may also stimulate bradycardia. In infants and children, never touch the back of the airway.
**ASSESSMENT TIPS**

Prior to suctioning—to avoid inserting the catheter too far into the oropharynx—the hard suction catheter can be measured with the tip placed at the angle of the jaw and a landmark established at the corner of the mouth.

- **Soft catheter**—The soft suction catheter consists of flexible tubing. It is also called a “French” catheter. It is used in suctioning the nose and nasopharynx and in other situations where the rigid catheter cannot be used. The length of catheter should be determined by measuring from the tip of the patient’s nose to the tip of his ear if it is being inserted in the nasopharynx or from the corner of his mouth to the tip of his ear if it is being inserted in the mouth and oropharynx. The soft suction catheter should not be inserted beyond the base of the tongue.

**Technique of Suctioning**

There are many suctioning techniques. They vary depending on the device and type of catheter used. One technique is described here (EMT Skills 10-1):

1. Position yourself at the patient's head. If this is not possible, take a position in which you can observe the airway.
2. Turn on the suction unit.
3. Select the appropriate type of catheter. Use a rigid catheter when suctioning the mouth or oropharynx. If the nasal passages need to be suctioned, select a soft (French) catheter and use low to medium suction (80–120 mmHg). A bulb syringe may be used if a soft catheter is not available.
4. Measure the catheter and insert it into the oral cavity without suction, if possible. Insert it no farther down than the base of the tongue.
5. Apply suction only on the way out of the airway. Begin suction after the tip has been positioned, moving the catheter tip from side to side to clear material from the mouth as the catheter is being removed. If possible, suction for no more than 15 seconds at a time in the adult; in infants and children, suction in shorter periods, approximately 5 seconds. However, it may be necessary to provide suction until the substance is clear from the airway to prevent aspiration from spontaneous or artificial ventilation.
6. If necessary, rinse the catheter with water to prevent obstruction of the tubing from dried or thick material. Do this by keeping a bottle of water available and applying suction to the water as necessary to clear the tubing.

**Special Considerations When Suctioning**

The following are special considerations when suctioning the airway:

- If the patient has secretions or vomitus that cannot be removed quickly and easily by suctioning, the patient should be log rolled onto his side and the oropharynx cleared by finger sweeping the foreign material from the mouth.
- If the patient in need of artificial ventilation is producing frothy secretions as rapidly as suctioning can remove them, apply suction for 15 seconds, provide positive pressure ventilation with supplemental oxygen for 2 minutes, then apply suction for another 15 seconds. Repeat this sequence until the airway is cleared.
- During suctioning, the residual volume of air in the lungs between respirations is removed. Residual volume is defined as the air remaining in the lungs after a maximal exhalation. This will cause a quick decrease in blood oxygen levels. Therefore, monitor the patient's pulse, heart rate, and pulse oximeter reading while suctioning. If the heart rate drops during suctioning, especially in infants and children, immediately remove the catheter, administer oxygen, and be prepared to begin positive pressure ventilation with supplemental oxygen.
- In the adult patient, a rapid heart rate (tachycardia), slow heart rate (bradycardia), or an irregular heart rate may be seen during suctioning. These can occur from stimulation of the airway by the suction catheter or may be an indication that the oxygen level in the blood is getting dangerously low. Stop the suction procedure and resume positive pressure ventilation for at least 30 seconds if the patient is being artificially ventilated.
- Before suctioning mucus and small amounts of secretions in a patient who is being artificially ventilated, ventilate him at a rate of 12 ventilations per minute for 5 minutes to wash out the residual nitrogen and increase the functional oxygen reserve. After suctioning, resume ventilation.

**Airway Adjuncts**

Once the airway is opened by the head-tilt, chin-lift maneuver or the jaw-thrust maneuver, and all foreign substances are removed by suctioning, it may be necessary to insert an airway adjunct to keep the airway open. There are two types of artificial airways: the oropharyngeal and nasopharyngeal. Both extend near the base of the tongue. Adjuncts are frequently used during artificial ventilation. When using these devices, keep the following points in mind:

- The adjunct must be clean and clear of obstructions.
- The proper size airway adjunct must be selected to avoid complications and ineffectiveness.
- The airway adjuncts do not protect the airway from aspiration of secretions, blood, vomitus, or other foreign substances into the lungs.
• The mental status of the patient will determine whether an adjunct can be used. The patient’s mental status must be continually and carefully monitored. If the patient becomes more responsive or gags, remove the airway adjunct.
• A head-tilt, chin-lift or jaw-thrust maneuver must still be maintained, even when an airway adjunct is in place and properly positioned.

**Oropharyngeal (Oral) Airway**

The oropharyngeal airway, also known as the oral airway, is a semicircular device of hard plastic or rubber that holds the tongue away from the back of the airway (Figure 10-19). The device also allows for suctioning of secretions. There are two common types of oropharyngeal airway: One is tubular and the other has a channelled side. Both are disposable and come in a variety of adult, child, and infant sizes.

The patient must be completely unresponsive and must have no gag or cough reflex. Do not use this device on a patient who is responsive or has a gag or cough reflex. If inserted in such a patient, it may cause vomiting or spasm of the vocal cords. This will further compromise the airway.

Use of an improperly sized airway adjunct can result in major complications. If the device is too long, it can push the epiglottis over the opening to the larynx, obstructing airflow to the trachea and causing a complete obstruction of the airway. Also, if not inserted properly it may push the tongue back into the airway, causing complete or partial obstruction.

Even with the adjunct properly inserted, it is often necessary to maintain the position of the patient’s head with a head-tilt, chin-lift or jaw-thrust maneuver to ensure an open airway. Airway management improves significantly with placement of the adjunct.

**Inserting the Oropharyngeal Airway.** The procedure for inserting an oropharyngeal airway is illustrated in EMT Skills 10-2. When inserting such a device, follow these steps:

1. Select the proper size airway. Measure the airway by holding it next to the patient’s face. A properly sized airway should extend the distance from the level of the front teeth to the angle of the jaw. Thus, the flange will be at the level of the teeth while the distal portion of the airway will be at the level of the angle of the jaw. An alternative method is to measure from the corner of the mouth to the tragus of the ear.

2. Open the patient’s mouth using the crossed-finger technique. In adults, insert the airway upside down, tip pointing to the roof of the mouth.

3. When the airway comes in contact with the soft palate at the back of the roof of the mouth, gently rotate it 180° while continuing to advance it until the flat flange at the top of the airway rests on the patient’s front teeth. The airway follows the natural curve of the tongue and the oropharynx (Figure 10-20). Following this procedure will reduce the chances of the tongue being pushed back and obstructing the airway. The airway can also be inserted sideways in the corner of the mouth and rotated 90° while it is being advanced into position.

An alternative method of inserting the oropharyngeal airway involves the use of a tongue depressor (blade). The tongue depressor is inserted in the mouth until its tip is at the base of the tongue. The tongue is then pressed down toward the mandible and forward with the tongue depressor. The airway is inserted in its normal anatomical position until the flange is seated on the teeth (Figure 10-21). This is the preferred method of airway insertion in infants and children.

If a patient at any time gags during the insertion, remove the oropharyngeal airway. It may then be necessary to use a nasopharyngeal airway or no adjunct at all. If a patient tries to dislodge the device after it has been inserted, remove it by gently pulling it out and down. Because this airway adjunct commonly causes the patient to gag, be prepared for vomiting.

![FIGURE 10-19 Oropharyngeal (oral) airways.](image-url)

![FIGURE 10-20 Oropharyngeal airway that is properly placed. The tongue is kept from falling back to occlude the patient’s airway.](image-url)
tube is lubricated, insertion is painful and may cause injury to the nasal mucosa, causing the nose to bleed and allowing blood to enter the airway, resulting in possible obstruction or aspiration. It is still necessary to maintain a head-tilt, chin-lift or jaw-thrust maneuver once the airway is inserted.

**Inserting the Nasopharyngeal Airway.** The procedure for inserting the nasopharyngeal airway is illustrated in EMT Skills 10-3. When inserting such a device, follow these steps:

1. Measure the airway by placing it next to the patient’s face. A properly sized airway should extend from the tip of the patient’s nose to the tip of the earlobe. It is also acceptable to measure the airway from the tip of the nose to the angle of the jaw. The diameter of the airway must be such that it can fit inside the patient’s nostril without blanching the skin of the nose.

2. Lubricate the outside of the airway well with a sterile, water-soluble lubricant. This will ease the insertion and lessen the chance of trauma to the nasal mucous lining.

3. Insert the device in the larger or more open nostril. The bevel should be facing the septum (wall between the nostrils) or floor of the nostril. The device is inserted close to the midline, along the floor of the nostril, and straight back into the nasopharynx. If you meet resistance, rotate the device gently from side to side as you continue to insert it. If you still meet resistance, remove the airway and try the other nostril. When the device is properly inserted, the flange should lie against the flare of the nostril (Figure 10-23).  

4. Check to be sure that air is flowing through the airway during inhalation and exhalation. If the patient is spontaneously breathing and no air movement is felt through the tube, remove it and attempt reinsertion in the other nostril.

Nasopharyngeal airways come in a variety of pediatric sizes. In very young patients, the nasopharyngeal airway is so small that it is easily obstructed by secretions and other upper airway substances. Children may have large adenoids, which will make insertion of the nasopharyngeal airway very difficult. This may also lead
to injury and bleeding. Even if insertion is possible, the large adenoids may compress the nasopharyngeal airway and increase the resistance in the airway. This may make the use of a nasopharyngeal airway in the very young ineffective.

### ASSESSMENT OF BREATHING

After establishing a patent airway, it is necessary to assess the adequacy of the patient’s breathing. Inadequate breathing leads to both poor gas exchange in the alveoli and ineffective delivery of oxygen to the cells. To determine whether the breathing is adequate, you must focus on both the rate at which the patient is breathing and the volume of each of his breaths.

#### Relationship of Tidal Volume and Respiratory Rate in Assessment of Breathing

It is imperative to assess the relationship between the volume, or amount of air taken in with each breath, and the rate at which the patient is breathing when determining whether the patient’s breathing is adequate or not. This is a key decision-making process that the EMT must accomplish quickly and accurately on every patient. The wrong decision about breathing status can have serious consequences, the most serious being death of the patient. Thus, understanding the basic relationship between the volume of air the patient breathes in, the respiratory rate, and the volume of air that actually reaches the alveoli is critical in determining whether the patient is breathing adequately and, if not, recognizing the need for immediate intervention with ventilation.

#### Minute Volume

Both adequate and inadequate breathing depend on two specific variables: the rate at which the patient is breathing and the depth of each breath. Because minute volume deals with both depth and rate, it typically correlates with how adequately the patient is breathing. A decrease in either the tidal volume or the respiratory rate may lead to a decrease in minute volume so severe that the patient is no longer moving an adequate amount of air per minute in and out of the lungs. The consequence will be a decrease in gas exchange at the level of the alveoli which, in turn, can cause the cells to become hypoxic.

It is not important for the EMT to determine the actual minute volume value; however, it is imperative to assess both respiratory rate and volume when determining whether the breathing is adequate, since a change in either of these could lead to inadequate breathing. If you arrive on the scene and ask your partner if the adult patient you are treating is breathing adequately and he answers that the respiratory rate is 14 per minute, you have only half the information necessary to determine whether the patient is breathing adequately or not. A respiratory rate of 14 per minute for an adult patient is well within the normal respiratory range. However, if that patient is moving only a very small volume into the lungs with each of the 14 breaths, he would have an inadequate breathing status and would need to be ventilated. On the other hand, if your partner were to tell you that a different adult patient is breathing full and deep, you can’t make a decision about the breathing status without also knowing the respiratory rate. If the respiratory rate is only six per minute in this patient, even though the volume with the six breaths is full and deep, the breathing would be considered inadequate and the patient would need to be ventilated. These examples reinforce the principle that you must know both variables, respiratory rate and tidal volume, before you can make any decision about the adequacy of breathing.

Typically, an increase in either the respiratory rate or the depth (tidal volume) would increase the respiratory minute ventilation. If a patient starts breathing at a faster rate, your assumption might be that he is moving more air in and out of the lungs in 1 minute, which would increase the minute volume and gas exchange in the alveoli of the lungs, thereby providing more oxygen to the cells. For example, if a patient has increased his respiratory rate from 12/minute to 20/minute, you might believe that the patient now has a greater minute volume because he is moving more air in and out of his lungs per minute. However, that would be true only if the tidal volume (depth of each breath) has remained at or near a normal level or has increased. A decrease in the tidal volume, even though the rate has increased, may have a profound negative effect on the volume of air reaching the alveoli and how much air is therefore available for gas exchange, as explained in the next section.

#### ASSESSMENT TIPS

The best method to assess for tidal volume is to look for adequate chest rise and to feel and listen for air movement from the nose and mouth.

#### Alveolar Ventilation

It is important to understand how the two variables just discussed, respiratory rate and tidal volume, determine the amount of air that actually reaches the alveoli, which is the site of gas exchange, as well as how they impact ventilatory management and oxygen therapy.

**Alveolar ventilation** is the amount of air breathed in that reaches the alveoli. Only the air that reaches the alveoli can be used for gas exchange (oxygenation of the blood and removal of carbon dioxide) since the trachea and bronchi do not participate in gas exchange.
Because of the effect of dead air space on ventilation, decreases in tidal volume can dramatically reduce the amount of air reaching the alveoli for gas exchange. As an example, take the average-sized adult who is breathing at 12 times per minute; however, because of a condition that depresses the respiratory system, he is only breathing in 200 mL of air (tidal volume) with each breath. The minute ventilation would be calculated as follows:

$$\text{Minute volume} = 200 \text{ mL} \times 12 \text{ per minute}$$
$$\text{Minute volume} = 2,400 \text{ mL}$$

Of the 200 mL of air taken in with each breath, 150 mL will fill the dead air space, leaving only 50 mL to reach the alveoli for gas exchange (200 mL of tidal volume – 150 mL of dead air space = 50 mL). Although the patient is still breathing at 12 times per minute, which is well within the normal range of breathing, the amount of air reaching the alveoli for gas exchange is thoroughly inadequate. If left untreated, the patient will become severely hypoxic. This patient needs to be immediately ventilated to increase the tidal volume so that the amount of air reaching the alveoli is increased to an adequate level. One might ask, if the patient is already breathing at 12 times per minute, how would that be done? When the patient begins to take in his own breath, the ventilation is delivered. The delivered volume of your ventilation will supplement and increase the tidal volume – 150 mL of dead air space = 50 mL. Although 150 mL will fill the dead air space, leaving only 50 mL to reach the alveoli for gas exchange (200 mL of tidal volume), the respiratory rate—needs ventilation.

Even though this patient is breathing 3½ times as fast as the patient breathing at 12 times per minute, he is getting less volume to his alveoli, creating a significantly inadequate breathing status.

As these examples have shown, it is necessary to carefully assess the tidal volume of the patient in addition to the respiratory rate, because a reduction in tidal volume affects the alveolar ventilation more drastically and leads to poor gas exchange sooner than rate disturbances. It is not your intent to determine an actual number value, but you must determine if the tidal volume is adequate. Also, as you can see by the example just given, an increased respiratory rate will not necessarily compensate for lower tidal volumes.

Remember that the dead space is filled with each breath regardless of the volume breathed in. If the average-sized patient is breathing in a tidal volume of only 200 mL with each breath, only 50 mL of air will reach the alveoli. This leads to severely inadequate breathing. A patient with an inadequate respiratory rate—or a poor tidal volume regardless of the respiratory rate—needs ventilation.

### Assessing for Adequate Breathing

The rate, rhythm, quality, and depth of respirations should be assessed. This is done by looking, listening, feeling, and auscultating (listening with a stethoscope).

- **Look (inspect).** Inspection includes the following:
  1. **Inspect the chest.** Observe for adequate expansion by watching the chest wall rise and fall. Look for retractions, or pulling inward, of the intercostal muscles of the chest as well as excessive use of the neck muscles during inspiration. In the unresponsive patient, you should place your ear near the patient’s mouth or nose while looking at the chest. You will simultaneously look, listen, and feel for air movement. If the chest does not rise adequately or appears to have a shallow rise, the tidal volume with each breath is inadequate. This patient needs to be ventilated.
  2. **Observe the patient’s general appearance.** Does he appear to be anxious, uncomfortable, or in distress? Is the patient lying down or sitting erect? (Typically, a patient who has difficulty in breathing is sitting up, leaning forward.) Does it appear that the patient is straining to breathe? Look for use or straining of the large muscle in the neck. This is often associated with a patient having a difficult time moving an adequate amount of air on inhalation.
  3. **Decide if the breathing pattern is regular or irregular.** Injuries to the brain commonly produce irregular breathing patterns that are ineffective.
  4. **Look at the nostrils** to see if they open wide during inhalation. Such flaring indicates difficulty in breathing.
The rhythm is checked by looking at the pattern of respirations (regular or irregular). The quality of breathing refers to assessment of tidal volume. It is assessed by inspecting for adequate chest rise with each inhalation. Also inspect for use of accessory muscles. Later in the assessment, the breath sounds will be assessed for presence or absence of breath sounds or abnormal noises.

**Adequate Breathing**

The patient whose breathing is adequate will exhibit the following characteristics (see Table 10-3):

**Rate.** The respiratory rate falls within a range of 8–24 respirations per minute for an adult, 15–30 per minute for a child, and 25–50 per minute for an infant. Elderly adults have resting respiratory rates of approximately 20 per minute. If the respiratory rates are too low, even though the tidal volume may be adequate, the patient will not move enough air into the lungs and alveoli to meet the oxygen demands of the cells of the body. The cells will become hypoxic and may eventually die. If the respiratory rate is too high, the fast rate may not allow the lungs to inflate fully with each breath, causing a decrease in the tidal volume with each breath. This will lead to a decrease in the volume of air getting to the alveoli for gas exchange, causing cells to become hypoxic.

Even though a range of 8–24 breaths per minute is listed as the normal range for the adult patient, it

</tbody>
</table>
is important that you assess the whole patient when considering rates as being outside a normal range. For example, in situations in which the patient is frightened or nervous, the respiratory rate will typically be elevated. A respiratory rate of >20/minute in a patient who is not in a stimulated state should be considered elevated, with the exception of the geriatric patient. This does not automatically mean that the patient’s breathing status is inadequate. Assess the patient for other signs of inadequate breathing, especially low or poor tidal volume, before intervening. As an example, you arrive on the scene and find a 22-year-old patient who just crashed his new car. He is alert and visibly upset. He is breathing at a rate of 28 times per minute. His speech is clear and appropriate, and he is completely oriented. He displays no other evidence of inadequate breathing. You would not decide to ventilate this patient based on the respiratory rate, even though it is outside the normal range. It is important that you consider the respiratory rates in relation to the whole patient. Typically, if the adult is breathing greater than 40 times per minute, the rate is so fast that the tidal volume will fall and the patient will need to be ventilated. Again, look for signs of inadequate tidal volume in the patient and do not ventilate purely based on the excessive rate.

**Rhythm.** The pattern is regular. Each breath is of about the same volume and comes at a regular interval. However, it is normal for a patient to sigh, which alters the pattern and makes it slightly irregular.

**Quality.** The breath sounds are equal and full bilaterally, indicating good expansion of each lung. The chest rises and falls adequately and equally with each breath. No excessive accessory muscle use is seen with inhalation and exhalation. It is normal for infants and children to use the abdominal muscles more than adults do in breathing; therefore, expect greater movement of the abdomen with these patients.

**Depth (tidal volume).** The chest will rise fully with each inhalation. The volume of air felt and heard by placing your ear next to the patient’s mouth and nose will be full and adequate with each breath.

A patient who is breathing adequately may, nevertheless, be in respiratory distress. **Respiratory distress** is a condition where the patient is working harder to breathe. The difficulty breathing may be from the patient working harder to move air into the lungs, out of the lungs, or both. The key to respiratory distress is that, even though the patient is working harder to breathe, the respiratory rate and tidal volume are still adequate. Because both are adequate, the patient does not need to be ventilated; however, he does need supplemental oxygen. Keep in mind that if, at any time, either the respiratory rate or tidal volume becomes inadequate, the patient needs to be ventilated.

### ASSESSMENT TIPS

For the patient to have adequate breathing he must have both an adequate tidal volume and an adequate respiratory rate.

### Inadequate Breathing

Inadequate breathing leads to both inadequate oxygen exchange at the level of the alveoli and inadequate delivery of oxygen to the cells. It also causes inadequate elimination of carbon dioxide from the body. If the breathing remains inadequate, the cells become hypoxic and begin to die. The brain, heart, and liver are the organs most sensitive to hypoxia. The brain will begin to die in about 4 to 6 minutes without an adequate oxygen supply.

Inadequate breathing may be categorized as respiratory failure or respiratory arrest. **Respiratory failure** occurs when the respiratory rate and/or tidal volume (amount of air breathed in and out) is insufficient. This results in hypoxia to the cells and organs. **Respiratory arrest**, also called apnea, occurs when the patient completely stops breathing. There is no movement of air; therefore, there is no rate or tidal volume. The patient quickly becomes hypoxic. Conditions that commonly cause respiratory arrest are:

- **Common Causes of Respiratory Arrest**
  - Stroke
  - Myocardial infarction (heart attack)
  - Drug overdose, especially opiates and other CNS depressants
  - Toxic inhalation (e.g., carbon monoxide poisoning)
  - Electrocution and lightning strike
  - Suffocation
  - Traumatic injuries to the head, spine, chest, or abdomen
  - Infection to the epiglottis
  - Airway obstruction by a foreign body

### ASSESSMENT TIPS

A patient who exhibits signs of respiratory failure or respiratory arrest requires immediate intervention with positive pressure ventilation.

A type of respiratory pattern that is completely inadequate and may be seen in witnessed cardiac arrest or in some other conditions is called agonal breathing or agonal respirations. Agonal respirations are gasping-type breaths. If seen in the cardiac arrest patient, they usually appear soon after the person goes into cardiac arrest. These are totally ineffective respirations. A patient with agonal respirations must be provided positive pressure ventilation. When agonal respirations are found in a patient who does not yet seem to be in cardiac arrest, immediately check the patient’s pulse, since these respirations are often found early in cardiac arrest.
It is important to recognize the signs of inadequate breathing and to immediately begin positive pressure (artificial) ventilation when they are present. Some of the signs are subtle and require careful evaluation (Figure 10-25 ■). If you are uncertain as to whether a patient requires breathing assistance, it is better to err on the side of safety and provide ventilation. Any time ventilation is assisted, oxygen must be connected and delivered with each ventilation.

**Signs of Inadequate Breathing**

**Figure 10-25** Signs of inadequate breathing and severe respiratory distress.

**Table 10-4** Signs of Inadequate Breathing

- Abnormal work of breathing
  - retractions
  - nasal flaring
  - abdominal breathing
  - diaphoresis
- Abnormal breath sounds
  - stridor
  - wheezing
  - crackles
  - silent chest (no breath sounds heard)
  - unequal breath sounds (trauma, infection, pneumothorax)
- Reduced minute ventilation
  - decreased tidal volume
  - inadequate respiratory rate
- Inadequate chest wall movement or chest wall injury
  - paradoxical chest wall movement
  - splitting of the chest wall
  - asymmetrical chest wall movement
- Irregular respiratory pattern (head injury, stroke, metabolic derangement, toxic inhalation)
- Rapid respiratory rate without clinical improvement in the patient’s condition

**Rate.** The respiratory rate is either too fast or too slow—outside the normal rate ranges that were listed under “Adequate Breathing.” *Tachypnea* is an excessively rapid breathing rate and may indicate inadequate oxygenation and breathing, especially in an adult. *Bradypnea* is an abnormally slow breathing rate and an ominous sign of inadequate breathing and oxygenation in infants and children. Bradypnea may also be seen in adult patients, particularly those with central nervous system depression, drug, or alcohol emergencies. Again, it is important to assess the patient for other signs of inadequate breathing, such as altered mental status; however, keep in mind that rate could be the single cause of inadequate breathing.

**Rhythm.** An irregular breathing pattern may indicate a severe brain injury or medical illness. Most irregular breathing patterns also produce an inadequate rate, depth, and quality.

**Quality.** Breath sounds that are decreased or absent indicate an inadequate volume of air moving in and out of the lungs with each breath. If the chest wall is not rising and falling adequately with each breath, or if the sides of the chest rise and fall unequally, the breathing is inadequate.

Inadequate breathing can lead to excessive use of the neck muscles and intercostal muscles during breathing in an attempt to increase the size of the chest, creating greater negative pressure and drawing in more air. This can produce retractions, or depressions between the ribs, above the clavicles, around the muscles of the neck, and below the rib...
cage with inspiration. These retractions are seen more often in infants and children.

- The abdomen may also move excessively in a patient breathing inadequately. Such a patient is using the abdomen to push up on the diaphragm in an effort to force air out of the lungs. Remember, however, that infants and children normally use their abdominal muscles in breathing.
- Infants may display a “seesaw” breathing motion in which the abdomen and chest move in opposite directions during breathing.
- The nostrils may flare during inspirations, an indication that a patient is working hard to breathe. Flaring is seen most often in children.
- **Depth.** The depth of breathing (tidal volume) is shallow and inadequate. The chest wall movement is minimal and does not rise adequately with inhalation. This is referred to as shallow breathing. Shallow breathing implies an inadequate tidal volume and requires assisted ventilation.

Not all of the signs of inadequate breathing will be present at the same time. *Any of these signs—a breathing rate that is too low or too high, a shallow depth, a poor quality, or an inadequate tidal volume—is by itself a reason to artificially ventilate a patient without delay. Waiting for additional signs to appear would only risk further compromise in the patient’s condition.*

### MAKING THE DECISION TO ASSIST VENTILATION OR NOT

A difficult decision that the EMT must make is whether the patient needs to be ventilated or if oxygen alone will be sufficient (EMT Skills 10-4). If the patient needs to be ventilated and you make the decision to simply place the patient on oxygen, it may mean the difference in whether the patient survives or dies. Recall from the previous discussion of alveolar ventilation that only the air getting to the alveoli is used in gas exchange. If a patient’s tidal volume is inadequate and only oxygen is placed on the patient, the tidal volume he is breathing may only be filling the dead air space and none or very little air is actually reaching the alveoli. The oxygen on the patient will be of very little use since the oxygen will stay within the dead air space and not reach the alveoli. Thus, placing oxygen on a patient with inadequate breathing is ineffective and will not prevent deterioration of the patient. It is necessary to get the air and oxygen to the alveoli. The only way that can be done is by ensuring that both the rate and the tidal volume of each breath are adequate to move oxygenated air into the alveoli for gas exchange.

Remember that neither rate nor depth by itself is enough to ensure that the breathing is adequate. You may, for example, determine that an adult patient is breathing at a rate of 16 respirations per minute, which falls within the normal limits. If you also note, however, that his chest shows only a slight rise and fall, that you hear and feel very little air being expelled, and that his breath sounds are diminished bilaterally, the patient’s breathing is inadequate. On the other hand, you might find a patient who has very good tidal volume but who is only breathing at 6 respirations per minute. Based on the rate, this patient’s breathing is also inadequate.

In order to have adequate breathing, the rate of respiration and the tidal volume must both be within adequate limits. If either is inadequate, the patient must be provided with positive pressure ventilation (artificial ventilation). This requires you to pay close attention to the chest wall activity during the assessment. If the chest wall is moving minimally, and very little air movement is heard or felt, you must immediately intervene and provide positive pressure ventilation to the patient. To reemphasize: Applying oxygen alone in this patient will be totally ineffective. It is necessary for you to closely monitor the respiratory rate and the chest wall movement continuously.

The need for ventilation is determined as follows:

**Adequate respiratory rate and an adequate tidal volume with each breath = Adequate breathing**

Thus, two adequates, rate and tidal volume, are necessary to have adequate breathing. When both adequates exist, there is no need for positive pressure ventilation. Adequate volumes of air are getting into the alveoli. This patient can be placed on an oxygen mask.

**Inadequate respiratory rate and an adequate tidal volume = Inadequate breathing**

Even though the patient may have an adequate tidal volume with each breath, the respiratory rate is not sufficient to maintain adequate breathing. This patient needs to be ventilated to move an adequate amount of air into the alveoli for gas exchange.

**Adequate respiratory rate and an inadequate tidal volume = Inadequate breathing**

This patient is breathing at an adequate rate; however, he is not moving enough volume with each breath to overcome the dead air space and place adequate amounts of oxygenated air into the alveoli for gas exchange. This patient needs to be ventilated.

To sum up how to determine the need for ventilation, remember the following (Table 10-5):

- Two adequates must be present to have adequate breathing: adequate respiratory rate and adequate tidal volume. (No need for ventilation. Supplemental oxygen can be applied if necessary.) Thus, it takes two adequates to produce adequate breathing!
and one who is receiving positive pressure ventilation. There are significant physiological differences in the characteristics of the situation and the resources available. Each method has different advantages and disadvantages; the method you select should be based on the characteristics of the situation and the resources available.

These differences may affect other body systems or require other management techniques:

- **Air movement.** In normal spontaneous ventilation, the negative pressure created by increasing the size of the thorax draws air into the lungs. Positive pressure ventilation is just that—you are delivering ventilation through positive pressure. You are forcing air into the lungs regardless of the pressure changes in the thorax. If a patient has a condition or injury that does not allow the thorax to expand adequately, such as a flail segment, there is not enough negative pressure generated to draw a sufficient amount of air into the lungs. With the application of positive pressure ventilation, the patient does not have to rely on his own ability to produce negative pressure; thus, in this situation, the treatment of choice is to force air into the lungs and the alveoli.

- **Airway wall pressure.** Airway wall pressure is not affected during normal ventilation. However, during positive pressure ventilation the airway walls are pushed outward creating a larger space. This requires higher volumes to fill the larger space and ventilate the patient effectively.

- **Esophageal opening pressure.** The esophagus is a soft, flexible structure. During normal ventilation, the esophagus remains collapsed and no air moves into it. Positive pressure ventilation can overcome the esophageal opening pressure, allowing air to enter the esophagus and filling the stomach with air during ventilation. This leads to gastric distention and the possibility of regurgitation, which increases the risk of compromising the airway and aspiration of gastric contents.

- **Cardiac output.** Normal spontaneous ventilation does not adversely affect the cardiac output or blood pressure. Actually, the negative pressure generated in the thorax prior to inhalation acts like a vacuum and sucks the venous blood into the inferior vena cava from the body below the level of the diaphragm. This provides an adequate amount of venous blood volume to the right side of the heart. Preload is dependent on the venous volume and amount of blood ejected from the right ventricle. An adequate preload contributes to an adequate stroke volume, cardiac output, and blood pressure. This is known as the cardiothoracic pump effect. During positive pressure ventilation, the thorax becomes positive during the inhalation phase as air is forced into the lungs. With the loss of the negative pressure generated during normal ventilation, the vacuum effect is diminished and the venous return decreases. This then decreases the preload, which in turn reduces the stroke volume, cardiac output, blood pressure, and perfusion. In a patient with no pulse who is in cardiac arrest or has a condition in which air is already trapped in the lungs, creating a more positive environment, such as with a severe asthma attack or tension pneumothorax, this effect can be significant and lead to poor perfusion of the brain, heart, and body.

**TABLE 10-5 Making a Decision: Should I Assist Ventilation or Apply Oxygen?**

<table>

</tr>
</tbody>
</table>

- Only one inadequate needs to be present to have inadequate breathing: **either** inadequate respiratory rate or an inadequate tidal volume. This patient needs to be ventilated. Placing an oxygen mask on the patient will not move the necessary volume into the alveoli for gas exchange. The patient will become hypoxic and will deteriorate. **Thus, it only takes one inadequate (rate or tidal volume) to produce inadequate breathing and the need for ventilation.**

**TECHNIQUES OF ARTIFICIAL VENTILATION**

The EMT can use several methods to artificially ventilate, or force air into, the patient who is breathing inadequately or not breathing at all. Because air is being forced into the patient’s lungs, the technique is referred to as **positive pressure ventilation (PPV).** The methods for providing positive pressure ventilation vary and require different levels of skill and different types of equipment. Each method has different advantages and disadvantages; the method you select should be based on the characteristics of the situation and the resources available.

**Differences Between Normal Spontaneous Ventilation and Positive Pressure Ventilation**

There are significant physiological differences in the patient who is breathing spontaneously (on his own) and one who is receiving positive pressure ventilation.
Adequate Ventilation

When performing artificial ventilation, regardless of the device being used, it is necessary to monitor the patient continuously to ensure that the ventilation is adequate. Inadequate ventilation may occur because of problems with the patient’s upper or lower airway or because of improper use of a ventilation device. You must be completely familiar with any device you use to ventilate a patient. Keep in mind that ventilation must not be interrupted for greater than 30 seconds.

Indications that the patient is being adequately ventilated (Figure 10-27a ■) include the following:

**Indications of Adequate Ventilation**

- The rate of ventilation is sufficient. Infants and children must be ventilated at a rate of 12–20 times per minute, once every 3 seconds (20 times per minute) to 5 seconds (12 times per minute) if a pulse is present. The rate for adults with a pulse is 10–12 times per minute, once every 6 seconds (10 times per minute) or once every 5 seconds (12 times per minute). Each ventilation should be delivered over 1 second. If the patient has no pulse, the ventilations are performed in conjunction with chest compressions at a ratio of 30 compressions to 2 ventilations in adults, children,
and infants (excluding newborns). A ratio of 15 compressions to 2 ventilations should be used in infants and children when two rescuers are available.

The rate of ventilation for a newborn infant with a pulse is 40–60 ventilations per minute. In the newborn with no pulse, the ratio of chest compressions to ventilations is 3:1 or 90 compressions to 30 ventilations.

- The tidal volume must be consistent; it must also be sufficient to cause the chest to rise during each ventilation. Inspect the chest with each ventilation to ensure adequate rise.
- The patient’s heart rate returns to normal. (Other underlying conditions may prevent return of a normal heart rate even when ventilations are adequately performed.)
- Color improves. The pale, gray, or cyanotic color begins to lessen and disappear.

**Inadequate Ventilation**

Indications of inadequate artificial ventilation (Figure 10-27b) include the following:

**Indications of Inadequate Ventilation**

- The ventilation rate is too fast or too slow. Ventilating a patient too rapidly does not allow for adequate exhalation and can also cause **gastric distention**. Too slow a rate of ventilation will not provide an adequate amount of oxygen. Other dangers associated with overventilating patients will be discussed later in the chapter.
- The chest does not rise and fall with artificial ventilation. This is an indication that the volume being delivered is not adequate. This may be due to a failure to use the ventilation device properly or to an airway obstruction. A common cause of ineffective ventilation is a poor mask seal that allows a portion of the ventilation to escape. If the patient’s chest does not fall, it may be a sign that the airway is not properly opened or that the ventilation device or the upper or lower airway is obstructed, preventing adequate exhalation.
- The heart rate does not return to normal with artificial ventilation. (Remember, however, to consider other sources of heart rate disturbance, such as blood loss, anxiety, or heart problems.)
- Color does not improve. The skin color remains extremely pale, cyanotic, or gray.

**ASSESSMENT TIPS**

An already rapid heart rate that continues to increase may be an indication of worsening hypoxia from inadequate ventilation. Conversely, a rapid heart rate that begins to decrease may indicate an improvement in the oxygenation and ventilation status; however, if the decrease in rate continues to bradycardia, it may be an indication of inadequate ventilation and oxygenation and worsening hypoxia.

**Cricoid Pressure**

Cricoid pressure (Sellick maneuver) (Figure 10-28a and 10-28b) was once thought to reduce complications associated with positive pressure ventilation when the unresponsive patient’s airway is not protected by an advanced airway device. The technique was intended to reduce the incidence of gastric inflation, regurgitation, and aspiration of gastric contents.

According to the American Heart Association guidelines of 2010, cricoid pressure is not recommended for routine use but can be used to facilitate insertion of an endotracheal tube in an adult. In the pediatric patient, cricoid pressure can be considered only if an extra EMT is available to apply the pressure without compromising the airway or effective ventilation and to guard against collapse of the trachea from excessive pressure.

---

![Cricoid Pressure Diagram](image-url)
Cricoid pressure may facilitate visualization of the glottic opening, the laryngeal opening that leads to the trachea, when an endotracheal tube is inserted during intubation (laryngoscopy). The backward pressure displaces the larynx posteriorly, allowing the intubator a better view of the opening. A paramedic or other advanced practitioner may ask you to apply cricoid pressure during laryngoscopy. Once the tube is in place, the cricoid pressure is released.

The technique to perform cricoid pressure is:

1. Locate the thyroid cartilage (Adam’s apple) by sliding index and middle fingers slowly down from the chin until you feel an obvious cartilage prominence.
2. Continue downward until you feel the base of the thyroid cartilage and, below it, a small, soft midline indentation, the cricothyroid membrane. Immediately below that membrane is the bulky cricoid cartilage.
3. Place your index finger on one side of the cricoid cartilage, your thumb on the other side, and apply firm backward pressure. Avoid completely compressing the cartilage.

The Backwards Upward Rightward Pressure (BURP) is another—and more effective—method to facilitate insertion of the endotracheal tube.

The cricoid cartilage is the only complete cartilaginous ring (review Figure 10-2). When forced backward, it may collapse the esophagus behind it against the cervical vertebrae, preventing air from traveling down to inflate the stomach and stomach contents from moving up. In this way, cricoid pressure protects the airway from regurgitation and consequent aspiration of stomach contents and also protects against gastric inflation. If the patient starts to regurgitate, release the cricoid pressure to prevent an esophageal tear. Immediately turn the patient onto his side, if possible, and suction the airway until clear.

Slow, sustained ventilation over 1 second with a controlled tidal volume is the best method to prevent gastric inflation. Also, proper positioning of the airway with the head-tilt, chin-lift maneuver will reduce resistance in the airway and allow more of the ventilation to flow down the trachea and into the lungs instead of down the esophagus and into the stomach.

Mouth-to-Mouth Ventilation

The air we breathe contains approximately 21 percent oxygen, 78 percent nitrogen, and 1 percent carbon dioxide and other gases. Of the 21 percent oxygen, only 5 percent is used by the body; the remaining 16 percent is exhaled. Dead air space, volume that was not used in gas exchange, makes the greatest contribution to maintaining a high oxygen content in the exhaled air. Because the exhaled breath contains about 16 percent oxygen, a patient can be oxygenated with the rescuer’s exhaled breath. This is the principle behind mouth-to-mouth ventilation taught in many first-aid and CPR courses.

Because ventilation devices such as a bag-valve device and pocket mask are routinely available, it is unlikely that the EMT will be required to perform mouth-to-mouth ventilation. There is a low risk of contracting an infectious disease from mouth-to-mouth ventilation.

Mouth-to-Mouth and Mouth-to-Nose Technique

The EMT forms a seal with his mouth around the patient’s mouth or nose and uses his exhaled air to ventilate. The nose is pinched during mouth-to-mouth ventilation, and the mouth is closed during mouth-to-nose ventilation. This technique provides adequate volumes of air for ventilating a patient. Its major limitations are the inability to deliver high concentrations of oxygen while ventilating and the risk posed to the EMT by contact with the patient’s body fluids. To reduce risks, a barrier device must be used.

Use mouth-to-nose ventilation when the patient’s mouth cannot be opened, when severe soft tissue or bone injury has occurred to the mouth or around it, in infants, or when you cannot achieve a tight mouth-to-mouth seal.

Mouth-to-Mask and Bag-Valve Ventilation: General Considerations

The next sections describe mouth-to-mask and bag-valve-mask ventilation. As you read about these techniques, keep in mind the general considerations regarding ventilation volumes, duration of ventilation, and gastric inflation.

Ventilation Volumes and Duration of Ventilation

When ventilating a patient by mouth-to-mask or bag-valve-mask technique, it is necessary to adjust the volume and rate of ventilation based on whether the patient has a pulse (Table 10-6). If the patient has a pulse (perfusing rhythm), the amount of air volume (tidal volume) delivered to the patient should be approximately 10 mL/kg (700–1,000 mL), enough to make the chest rise adequately and effectively with each ventilation. The ventilation rate in the adult patient with a pulse is 10–12 breaths per minute (one breath every 6 to 5 seconds, respectively). The pediatric patient, from 1 year of age to 12–14 years of age (adolescent), is ventilated at 12–20 times per minute (5 to 3 seconds, respectively) when a pulse is present. The infant who is less than 1 year of age is ventilated at 12–20 times per minute (5 to 3 seconds, respectively) when a pulse is present. In every patient, the ventilation
is delivered over a 1-second period. The rate of ventilation for a newborn infant with a pulse is 40–60 ventilations per minute.

If the patient is pulseless (no perfusing rhythm), the ventilation rates are reduced and are performed in conjunction with chest compressions. The compression-to-ventilation ratio in the adult patient for both one- and two-person CPR is 30 compressions to 2 ventilations. For the infant and child, when one-person CPR is performed, the ratio remains at 30 compressions to 2 ventilations; however, in the infant and child, the ratio changes to 15 compressions to 2 ventilations when two-person CPR is performed. In the newborn with no pulse, the ventilation rate is approximately 30 per minute being performed in conjunction with chest compressions. This is done at a ratio of 3 compressions to 1 ventilation. Each ventilation in the pulseless patient, regardless of age, should be delivered over 1 second. The volume of air delivered should be enough to make the chest visibly rise with each ventilation.

At any time a patient is being ventilated, an airway adjunct must be inserted to facilitate maintenance of the
Mouth-to-mask ventilation is the preferred method to use when performing artificial ventilation because of the following advantages:

- One EMT can ventilate using the two-handed mask seal technique, achieving a better mask seal.
- The mask eliminates direct contact with the patient's nose, mouth, and secretions.
- Use of a one-way valve at the ventilation port prevents exposure to the patient's exhaled air.
- The method can provide adequate tidal volumes and possibly greater tidal volumes than bag-valve-mask ventilation.
- Supplemental oxygen can be administered through the oxygen inlet that most pocket masks have in addition to the ventilation port.

Disadvantages of mouth-to-mask include the following:

- The mask is perceived by some EMTs as having an increased risk of infection.
- The EMT providing the ventilation may fatigue after a period of time.
- The device doesn't allow for the highest possible concentration of oxygen to be delivered with each ventilation.

The mask used to ventilate the patient must have the following characteristics:

- It should be of a transparent material to permit the detection of vomitus, secretions, blood, or other substances in the patient's mouth.
- It must be able to fit tightly on the patient's face and form a good seal.
- It must have an oxygen inlet to allow for high-concentration oxygen delivery at 15 liters per minute (lpm).
Mouth-to-Mask Technique—
No Suspected Spine Injury

Mouth-to-mask ventilation is illustrated in Figure 10-30. The procedure is described as follows:

1. Connect a one-way valve to the ventilation port of the mask and connect tubing that is attached to an oxygen supply to the oxygen inlet. Set the oxygen flow for 15 lpm.
2. Position yourself, if possible, at the top of the patient’s head. This is referred to as a cephalic technique. It is easier to monitor the patient’s chest rise and fall in this position. However, if you are performing one-person CPR, it is better to position yourself to one side of the patient’s head. This is called a lateral technique. It is the preferred technique when performing one-person CPR because it allows easier movement from the chest to the airway to provide both chest compressions and ventilations.
3. Place the mask on the patient’s face. The narrow top portion of the mask should be seated on the bridge of the nose, and the broader portion should be seated in the cleft above the chin. Hold the mask with a “C-E” technique. Place your thumbs on the top and lateral edges of the mask, the thumb sides of your palms along the sides of the mask, and your index fingers over the bottom of the mask over the cleft above the chin. In this way, your thumbs and index fingers form “Cs” around the mask chimney. With your middle, ring, and little fingers, grasp under the mandible just in front of the earlobes, forming “Es” with those fingers. Pull upward on these fingers, using the “Es” to lift the mandible upward and lift the chin. Be careful to keep the patient’s mouth open if no oropharyngeal or nasopharyngeal airway is in place. While lifting the mandible upward, tilt the head backward, performing a head tilt while achieving a chin lift by lifting the mandible to the mask. Squeeze the mask tightly to achieve an airtight seal between the mask and the patient’s face.
4. Place your mouth around the one-way valve and blow into the ventilation port of the mask. Give a breath over a 1-second period. When the chest rises adequately, stop the ventilation to allow for exhalation. If you cannot ventilate, or if the chest does not rise adequately, reposition the patient’s head and try again. Improper head position is the most common cause of difficulty with ventilation. If the second try also fails, assume the airway is blocked by a foreign object and follow the guidelines for removing a foreign body airway obstruction that you learned in your basic cardiac life support course.

Mouth-to-Mask Technique—
Suspected Spine Injury

If the patient has a suspected spine injury, you will ventilate the patient with the mouth-to-mask technique, taking care not to manipulate the head and neck during the procedure. Mouth-to-mask ventilation in the patient with a suspected spine injury would be performed as follows:

1. Connect a one-way valve to the ventilation port of the mask and connect tubing that is attached to an oxygen supply to the oxygen inlet. Set the oxygen flow for 15 lpm.
2. Position yourself, if possible, at the top of the patient’s head or at the side.
3. Place the mask on the patient’s face. The narrow top portion of the mask should be seated on the bridge of the nose, and the broader portion should be seated in the cleft above the chin. Hold the mask with a “C-E” technique. With your middle, ring, and little fingers, grasp under the angle of the mandible just in front of the earlobes. Pull upward on the angle of the jaw to lift the mandible upward and to lift the chin forward without tilting the head backward and while keeping the head and neck in a neutral position (jaw-thrust maneuver). Squeeze the mask tightly to achieve an airtight seal between the mask and the patient’s face.
4. Deliver the ventilation as you would in the non-spine-injured patient.

If the patient is in cardiac arrest (painless) and an open airway cannot be established or the patient cannot be adequately ventilated by using the jaw-thrust maneuver, it may be necessary to perform a head-tilt, chin-lift maneuver to gain an adequate airway and ventilation of the patient. This can be done by continuing to slightly lift the patient’s head backward until the airway is achieved. As soon as the airway is achieved,
stop, maintain spinal stabilization, and begin to ventilate the patient. It may be necessary to reposition the airway several times while chest compressions are being performed.

**Ineffective Ventilation**

If the ventilations are ineffective and are not producing adequate chest rise and fall, it is necessary to immediately identify and correct the problem. Ineffective ventilation may be due to several possible causes. If the chest does not rise adequately during ventilation with any ventilation device, perform the following sequence to identify and correct possible causes of the problem:

1. **Reposition the head and neck** to ensure the airway is open. In a suspected spine injury, reposition the jaw thrust while keeping the head in a neutral position. If the jaw thrust is ineffective in opening or maintaining an airway, use the head-tilt, chin-lift maneuver to ventilate the patient, even if the potential for a spine injury exists. Opening the airway and providing adequate ventilation is a priority in patients in cardiac arrest and takes precedence over other procedures, even with suspected spine injury.

2. **Change from a head-tilt, chin-lift to a jaw-thrust maneuver or from a jaw-thrust to a head-tilt, chin-lift maneuver if the patient is in cardiac arrest.**

3. **Readjust the face mask** and make sure there are no seal leaks between the face and the mask.

4. **Administer a greater tidal volume.** The tidal volume may be insufficient to ventilate the patient adequately, especially in patients with a history of airway and lung disease, or if the patient’s condition is related to an airway problem (such as an acute asthma attack or allergic reaction), chest injury (such as a collapsed lung), or lung condition (such as pneumonia).

5. **Insert an oropharyngeal or nasopharyngeal airway to assist in maintaining an open airway.**

**ASSESSMENT TIPS**

When using a jaw-thrust maneuver in a patient with suspected spinal injury, if you are unable to ventilate the patient after several attempts, you can slightly extend the head until a decrease in airflow resistance is felt and the chest rises adequately with each ventilation.

**Bag-Valve-Mask Ventilation**

A **bag-valve-mask (BVM) device** (Figures 10-31a and 10-31b) is a manual resuscitator used to provide positive pressure ventilation. The bag-valve mask consists of a self-inflating bag, a one-way nonrebreather valve, a face mask, an intake/oxygen reservoir valve, and an oxygen reservoir. Other features may include medication ports to deliver aerosolized and other medications, suction ports for clearing the airway, and ports to sample the end-tidal CO₂. Most adult-sized BVM devices have a volume of approximately 1,600 milliliters. In the adult, deliver approximately 600 mL with each ventilation. In the prehospital setting it is difficult for the EMT to gauge the mLs of volume of air delivered. Therefore, ensure that each ventilation delivered is enough to produce chest rise over 1 second. Bag-valve-mask devices used for ventilation of full-term newborns, infants, and children should have a minimum volume of 450–500 mL.
In children 8 years of age or greater, use an adult BVM device. In infants and children, chest rise should also be used to gauge an adequate tidal volume delivered with each ventilation.

Regardless of the size of the BVM, be sure to use only enough volume to cause the chest to rise. When used without an oxygen source, the device will only deliver 21 percent oxygen, the amount found in room air. By adding oxygen and a reservoir, you can deliver close to 100 percent oxygen to the patient, a major advantage of using the device.

The principal advantages of the BVM device over mouth-to-mask ventilation are its convenience for the EMT and its ability to deliver enriched oxygen mixtures. Also, if two EMTs are performing the procedure, one EMT achieves and maintains the mask seal with two hands, while the second EMT squeezes the bag to deliver the ventilation. However, the bag-valve mask may not consistently generate the tidal volumes that are possible with mouth-to-mask ventilation during one-EMT bag-valve-mask use. Thus, a disadvantage of the BVM device is the need for two EMTs to perform a two-handed mask seal to typically achieve the best ventilation results.

The BVM device is harder to use than it looks and is fatiguing to the operator when performing a one-person technique. The EMT must simultaneously provide a tight mask seal, maintain an open airway by properly positioning the patient’s head and chin, and squeeze the bag to deliver the ventilation. It takes frequent practice to maintain the skills needed to deliver adequate ventilation with the device. Because of the difficulty in working the bag-valve mask, use of the device by two persons is highly recommended but not always possible. A single-operator mask such as the pocket mask has few of these disadvantages, takes less skill and maintenance, and is much easier to use by all practitioners, experienced or inexperienced.

A bag-valve mask should have these features:

- A self-refilling bag that is disposable or easy to clean and sterilize.
- A nonjamming valve system that allows a maximum oxygen inlet flow of 30 lpm.
- Either no pop-off valve or a pop-off valve that can be manually disabled. A pop-off valve that is not disabled may lead to inadequate ventilation.
- Standard 15/22 couplings for masks, endotracheal tubes, tracheostomy tubes, laryngeal mask airways, and Combitubes.
- An oxygen inlet and a reservoir that can be connected with an oxygen source to deliver high concentrations of oxygen during ventilation. An oxygen reservoir should be used when ventilating all patients.
- A true nonrebreather valve that vents the patient’s exhalations and does not allow him to rebreathe any exhaled gas and cannot be obstructed by foreign material.
- Adaptability to all environmental conditions and temperature extremes.

Outline

1. MTs. For reasons already cited, use of the device by two EMTs is preferred. One EMT holds a tight mask seal with both hands while the second EMT uses both hands to squeeze the bag to deliver the full volume of oxygenated air inside it (Figure 10-32). This technique is considerably more effective than one-person use of the device and should always be employed unless the number of personnel or the circumstances of the run, such as an extremely cramped working area, do not allow it.

Two-Person BVM Technique.

1. If possible, position yourself at the top of the patient's head. If you do not suspect a spinal injury, open the airway using the head-tilt, chin-lift maneuver. Raise the patient’s head slightly with a towel or pillow to achieve a better sniffing position. If a spinal injury is suspected, follow procedures described later under “Bag-Valve-Mask Technique—Patient with Suspected Spinal Injury.”
2. Select the correct size mask and bag-valve device. If the patient is unresponsive, an oropharyngeal or nasopharyngeal airway should be inserted to help maintain a patent airway.
3. Place the upper, narrower part of the mask over the bridge of the nose and lower it over the mouth and into the cleft above the chin. If the mask has a large

Bag-Valve-Mask Technique—No Suspected Spine Injury

A bag-valve-mask device can be used by one or two EMTs. For reasons already cited, use of the device by two EMTs is preferred. One EMT holds a tight mask seal with both hands while the second EMT uses both hands to squeeze the bag to deliver the full volume of oxygenated air inside it (Figure 10-32). This technique is considerably more effective than one-person use of the device and should always be employed unless the number of personnel or the circumstances of the run, such as an extremely cramped working area, do not allow it.

Two-Person BVM Technique. Procedures for two-person use of the bag-valve mask are as follows:

1. If possible, position yourself at the top of the patient's head. If you do not suspect a spinal injury, open the airway using the head-tilt, chin-lift maneuver. Raise the patient’s head slightly with a towel or pillow to achieve a better sniffing position. If a spinal injury is suspected, follow procedures described later under “Bag-Valve-Mask Technique—Patient with Suspected Spinal Injury.”
2. Select the correct size mask and bag-valve device. If the patient is unresponsive, an oropharyngeal or nasopharyngeal airway should be inserted to help maintain a patent airway.
3. Place the upper, narrower part of the mask over the bridge of the nose and lower it over the mouth and into the cleft above the chin. If the mask has a large

![Image](https://via.placeholder.com/150)
round cuff surrounding the ventilation port, center the port over the mouth (Figure 10-33 ■).

4. Position your thumbs over the top half of the mask and your index fingers over the bottom portion of the mask. Use your ring and little fingers to bring the patient’s jaw up to the mask. The middle fingers, depending on the size of the EMT’s hands, may be placed either under the mandible or over the mask. The thumb-side edges of the palms are placed over both sides of the mask to hold it in place and form an airtight seal. This forms the “E-C” hand position, as previously described.

5. Have another EMT connect the bag valve to the mask, if it is not already attached.

6. Begin ventilation as soon as possible. The other EMT or qualified person will squeeze the bag with two hands and deliver the ventilation steadily over 1 second while watching for adequate chest rise. Oxygen must be connected to the reservoir of the BVM and flowing at 15 lpm as quickly as possible. If you cannot ventilate or if the chest does not rise adequately, take the measures that will be described under “Bag-Valve-Mask Problems.”

7. An adult with a pulse should be ventilated once every 5 to 6 seconds (10–12 breaths/minute) and infants and children once every 3 to 5 seconds (12–20 breaths/minute). Review Table 10-6 for ventilation rates in the pulseless patient. The chest should be monitored continuously for adequate rise and fall.

**One-Person BVM Technique.** When you must operate the bag-valve mask alone, apply the mask to the patient’s face with one hand. Your thumb should be placed over the part of the mask covering the bridge of the nose, and your index finger is placed over the part covering the cleft above the chin. Seal the mask firmly on the face by pushing down with the thumb and index finger while pulling up on the mandible with the other fingers to maintain a head-tilt, chin-lift. The “E-C” hand position technique will be performed with only one hand. Squeeze the bag with the other hand while observing the chest rise to make certain the lungs are being inflated effectively (Figure 10-34 ■). The bag may alternatively be compressed against your body or forearm to deliver a greater tidal volume to the patient. If you are performing one-person BVM, ventilate the patient for approximately 1 minute and then connect the oxygen to the BVM. Be sure that you do not interrupt ventilation for more than 30 seconds when doing so.

**Bag-Valve-Mask Problems.** If you are ventilating with a bag-valve mask and the patient’s chest does not rise and fall, reevaluate the BVM device and the patient’s airway, considering these possible problems and remedies:

1. **Check the position of the head and chin.** Reposition the airway and repeat your attempt at ventilation.

2. **Check the mask seal** to ensure that an excessive amount of air is not escaping from around the mask. Reposition your fingers and the mask to attain a tight seal.

3. **Assess for an obstruction.** If the airway is repositioned, the seal is adequate, and you are still unable to ventilate effectively, consider an airway obstruction. Inspect inside the mouth for evidence of an obstruction. If one is found, remove it with a finger sweep. If none is found, and apply foreign body airway obstruction clearance maneuvers until you are able to effectively ventilate.

4. **Check the bag-valve-mask system** to ensure that all the parts are properly connected and operational. Some systems with a bag-type oxygen reservoir will refill extremely slowly if the oxygen flow rate is inadequate. This causes a reduction in the tidal volume delivered to the patient and subsequently produces minimal chest rise and fall and leads to hypoxia.

5. **If the chest still does not rise and fall,** use an alternative method for positive pressure ventilation, for example, a pocket mask or a flow-restricted, oxygen-powered ventilation device.

6. **If you are having difficulty maintaining an open airway,** insert an oropharyngeal or nasopharyngeal airway. Either device will help keep the tongue from falling back to block the airway.

[FIGURE 10-33] Always use the proper size mask. It should fit securely over the bridge of the nose and in the cleft above the chin.

[FIGURE 10-34] One-person bag-valve-mask method.
7. If the patient’s abdomen rises with each ventilation or it appears to be distended, it may be an indication of one of the following:
   • The head-tilt, chin-lift maneuver is not being performed properly and is allowing an excessive amount of air into the esophagus and stomach. Reposition the head and neck and resume ventilation.
   • The patient is being ventilated too rapidly or with too great a tidal volume. Such excessive ventilation increases the pressure in the esophagus and allows air to enter the stomach. Squeeze the bag slowly to deliver the volume over a 1-second period and allow for adequate exhalation after each ventilation. Ensure that an excessive tidal volume is not being delivered and causing the stomach to fill with air.

Bag-Valve-Mask Technique—Patient with Suspected Spinal Injury

If you suspect a patient has a spinal injury, you must establish and maintain in-line spinal stabilization as a priority. The airway maneuvers and use of the bag-valve-mask technique must be performed with special care to avoid movement of the head or spine while maintaining in-line spinal stabilization until the patient is fully immobilized to a backboard. The procedures for using a bag-valve mask with a patient with suspected spinal injury are illustrated in EMT Skills 10-5 and are described here:

1. While following procedures for manual in-line stabilization of the head and neck (see Chapter 32, “Spinal Column and Spinal Cord Trauma”), open the airway using a jaw-thrust maneuver.
2. Have another EMT or a trained assistant maintain the in-line stabilization of the head and neck while you select the correct size mask. If no other personnel are available, you can kneel at the patient’s head and hold his head between your thighs and knees to prevent movement.
3. Position your thumb over the top portion of the mask and your index finger over the bottom portion of the mask. Use your ring and little fingers to bring the patient’s jaw up to the mask. The middle finger, depending on the size of your hands, may be placed either under the mandible or over the mask. Place the top of the mask over the bridge of the nose. Lower the mask over the mouth until the bottom half of the mask fits snugly in the cleft above the chin. Place the thumb-side edge of your palm over the side of the mask to hold it in place and form an airtight seal. This forms the “E-C” hand position, as previously described.
4. Place the mask to the face and bring the jaw up to the mask without tilting the head back or moving the neck.
5. Have another EMT connect the bag-valve device to the mask, if this has not already been done. Hold a mask seal with your thumbs at the bridge of the nose and the index fingers over the bottom half of the mask. The edges of the palms on the thumb side should hold the mask down on the face. The middle, ring, and little fingers are used to maintain the jaw thrust. EMTs with smaller hands may be able to form the “E-C” position with the thumb, index, and middle fingers and grasp the mandible only with the ring and little fingers.

6. Begin ventilation as soon as possible. Have the other EMT or trained assistant squeeze the bag with two hands to deliver the volume over a 1-second period.
7. An adult with a pulse should be ventilated once every 5 to 6 seconds (10–12 breaths/minute) and infants and children once every 3 to 5 seconds (12–20 breaths/minute). Review Table 10-6 for ventilation rates in the pulseless patient. The chest should be monitored continuously for adequate rise and fall.
8. If the bag-valve mask has not already been connected to the oxygen supply, the patient should receive positive pressure ventilation for 1 minute. At that point the other EMT should make the connection, set the flow at 15 lpm, attach a reservoir, and resume ventilation. Ventilation should not be interrupted for more than 30 seconds at any time.
9. In-line manual stabilization must be maintained until the patient is completely immobilized to the backboard.

10. Once the patient is fully immobilized, follow the standard two-person bag-valve-mask technique, using the jaw-thrust maneuver to maintain a patent airway. If the patient is in cardiac arrest and the airway cannot be established with a jaw-thrust maneuver, it may be necessary to tilt the head until the airway can be established. The priority in the cardiac arrest patient is airway management and effective ventilation.

   If only two EMTs are at a scene, it may be necessary for one to hold the in-line stabilization with his thighs and knees, while performing all the additional steps of the one-person bag-valve-mask technique. This is the most ineffective method for providing bag-valve-mask ventilation and should be replaced with the two-person technique as soon as possible. Also apply cricoid pressure, if enough personnel are available, to reduce the risk of gastric inflation, regurgitation, and aspiration.

Flow-Restricted, Oxygen-Powered Ventilation Device (FROPVD)

Another method of providing positive pressure ventilation is through the flow-restricted, oxygen-powered ventilation device (FROPVD), also known as a manually triggered ventilation (MTV) device. The device is powered by oxygen and, with a proper mask seal, will deliver 100 percent oxygen to the patient. In the spontaneously breathing patient, the valve is opened automatically by the negative pressure created by the...
The FROPVD should have the following features:

- Rugged, compact design, easy to hold and operate
- Can be used with advanced alternative airways

**FROPVD Techniques**

Follow the steps described next when using a flow-restricted, oxygen-powered ventilation device:

1. Check the unit to ensure it is properly functioning. Also, check the oxygen source to ensure there is an adequate supply to operate the unit effectively.
2. Open the airway using a head-tilt, chin-lift maneuver if no spinal injury is suspected (Figure 10-35a ■). If a spinal injury is suspected (Figure 10-35b ■), use the same technique of establishing a mask seal with a jaw thrust as described in the bag-valve mask section. Insert an oropharyngeal or nasopharyngeal airway. Apply the adult mask to the patient's face in the same manner as for the bag-valve mask.
3. Connect the flow-restricted, oxygen-powered ventilation device to the mask if not already done.
4. Activate the valve by depressing the trigger or button on the valve. As soon as the chest begins to rise, deactivate the valve by releasing the trigger or button. The oxygen flow ceases and the patient's exhaled gas is released through a one-way valve. The device is driven by 100 percent oxygen; thus, there is no need to attach any supplemental oxygen source once ventilation has begun.
5. An adult with a pulse should be ventilated once every 5 to 6 seconds (10–12 breaths/minute). The adult patient in cardiac arrest will be ventilated twice after every 30 compressions. The chest should be monitored continuously for adequate rise and fall.

**FIGURE 10-35**  (a) A flow-restricted, oxygen-powered ventilation device on a patient with no suspected spine injury. (b) A flow-restricted, oxygen-powered ventilation device on a patient with a suspected spine injury.
If you suspect that a patient has a spinal injury and two EMTs are available, one can perform the in-line stabilization while the other holds a mask seal and triggering the device. If only one EMT is available, he can hold in-line stabilization of the head and neck with his thighs and knees while holding a mask seal and triggering the device.

**FROPVD Problems.** If a patient’s chest does not rise adequately during use of the flow-restricted, oxygen-powered ventilation device, reevaluate the position of the head and chin and the mask seal. If the chest does not rise after repositioning and the mask seal proves adequate, an airway obstruction is a possibility; follow the procedures for adult foreign body airway obstruction clearance.

If the oxygen source that powers the device runs out or the user cannot effectively use the device, it is necessary to use an alternative means to ventilate the patient, such as pocket mask or bag-valve-mask device.

### Automatic Transport Ventilator (ATV)

Another device used for positive pressure ventilation is the **automatic transport ventilator (ATV)** (Figure 10-36). Several different devices are available. They have been shown to be excellent at providing and maintaining a constant rate and tidal volume during ventilation, and maintaining adequate oxygenation of arterial blood. In addition, most ATVs use oxygen as their power source, thereby delivering 100 percent oxygen during ventilation.

The ATV can deliver oxygen at lower inspiratory flow rates and for longer inspiratory times. Therefore, the devices have a lesser likelihood of causing gastric distention compared with other methods of positive pressure ventilation, including mouth-to-mask and bag-valve-mask ventilation. However, as with any ventilation device, gastric distention can occur if the patient’s head and neck are improperly positioned.

Among other advantages of the ATV are the following:
- The EMT is free to use both hands to hold the mask and maintain the airway position as the device delivers the ventilation automatically.
- The device can be set to provide a specific tidal volume, respiratory rate, and minute ventilation.
- Alarms indicate low pressure in the oxygen tank as well as accidental disconnection of the ventilator.
- One EMT can hold in-line stabilization with his thighs and knees and hold the mask seal with two hands while the ventilation is delivered.

There are a few disadvantages associated with the ATV:
- Because the ATV is usually oxygen powered (although one type of ATV does use electric power), once the oxygen supply is depleted, the device cannot be used. A pocket mask or bag-valve-mask device must always be available when using an ATV in case of failure or oxygen depletion.
- Some ATVs cannot be used in children less than 5 years of age.
- When using the ATV device, it is not possible to feel an increase in airway resistance or a decrease in the compliance in the lungs.

### ATV Recommended Features

ATVs used for prehospital care should have the following features:
- A device that is simple and time- or volume-cycled (pressure-cycled devices should be avoided)
- A standard lightweight 15/22 mm connector
- Lightweight (less than or equal to 4 kg) and rugged in design that can function in temperature extremes
- A default peak inspiratory pressure limit of 60 cm H₂O that is adjustable from 20 to 80 cm H₂O and easily accessible to the EMT
- An audible alarm that indicates the peak inspiratory pressure is generated and alerts the EMT that the lung compliance is low or the airway pressure is high, which results in a lower delivered tidal volume
- Ability to deliver 50–100 percent oxygen
- An inspiratory time of 1 second
- An adjustable inspiratory flow of 30 lpm for the adult and 15 lpm for the child
- A rate of 10 breaths per minute for adults and 20 breaths per minute for children

Some ATVs have a demand valve built in, in the event that the patient begins to breathe spontaneously. The valve should be able to deliver a peak inspiratory flow rate of 120 lpm. Also, it is necessary that the ATV have an appropriate inspiration-to-exhalation ratio of 1:2 seconds. Some ATVs have alarms that indicate low oxygen levels, disconnection from the mask, or a low battery. The ATV may also have the ability to provide positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). Those using an ATV must be specially trained and well aware of the device and its specific features.
**ATV Techniques**

It is necessary to consult with medical direction to determine the ventilator settings when using the ATV. Always follow the manufacturer's recommendations. The following are general guidelines for the operation of an ATV:

1. Check the ATV to ensure it is properly functioning.
2. Attach the ATV to a mask. Seal the mask on the face by using the same technique described earlier in the bag-valve mask section.
3. Select the appropriate tidal volume and rate to be delivered. On some models the tidal volume and rate are preset. Turn the unit on.
4. Observe the chest for adequate rise and fall. Adjust the tidal volume until adequate rise of the chest is achieved.
5. Continuously monitor both the device for proper functioning and the rise of the patient's chest for adequate ventilation. If a failure of the device is detected or suspected, immediately discontinue use of the ATV and begin ventilation with a pocket mask or a bag-valve-mask device.

**Ventilation of the Patient Who Is Breathing Spontaneously**

If the patient presents with either an inadequate respiratory rate or an inadequate tidal volume, even though he is still breathing, it is necessary to ventilate the patient and provide supplementary oxygen to ensure that he is receiving an adequate alveolar ventilation volume. The most important step is to assess accurately and recognize the need for ventilation of the patient who is breathing, but breathing inadequately. Signs of inadequate breathing include an altered mental status, inadequate respiratory rate, poor chest rise and fall, and fatigue from an increased work of breathing.

Complications that you may encounter when ventilating a spontaneously breathing patient include combativeness in the hypoxic patient who does not cooperate, an inadequate mask seal, overventilation leading to lung injury, and risk of regurgitation and aspiration.

Explain the procedure to any patient with spontaneous ventilation who requires positive pressure ventilation. Coach the patient to work with you during the ventilation. You may not know if the patient can understand; regardless, it is necessary to explain what you are doing in case he can understand but is unable to respond appropriately.

The following breathing patients would need ventilation:

- **The patient with an adequate respiratory rate but an inadequate tidal volume (shallow breathing).** This is termed hypopnea (low volume of breathing). The rate is adequate; however, the tidal volume is inadequate. Because the ventilation rate is adequate, you would assist the ventilation at the rate at which the patient is already breathing. When the patient begins to inhale, you would deliver your ventilation, ensuring an adequate tidal volume with each ventilation. Be sure to connect supplemental oxygen, and watch for chest rise with each ventilation.

- **The patient who has an adequate tidal volume but has a respiratory rate that is too fast.** This is termed bradypnea (slow breathing). Even though the tidal volume of each breath may be adequate, the rate is not fast enough to maintain adequate oxygenation of the tissues. In the patient with bradypnea, you would need to supplement ventilation to bring the rate to 10–12 in the adult and 12–20 in the infant or child. For example, if the adult patient was breathing only six times per minute, you would need to deliver another six breaths in 1 minute to achieve an adequate minute volume. Begin by ventilating with each of the patient's inhalations and then, over the next 5–10 ventilations, increase the rate to once every 5–6 seconds. Be sure that each breath the patient takes on his own has an adequate tidal volume. If not, as the patient begins to inhale, deliver a ventilation and then deliver another ventilation within 5–6 seconds to achieve an adequate ventilation rate.

- **The patient who has a respiratory rate that is too fast (tachypnea) that leads to an inadequate tidal volume (hypopnea).** You must deliver ventilations at a rate of 10–12 per minute with an adequate tidal volume with each ventilation. As an example, if the adult patient is breathing at a rate of 42 per minute and the tidal volume is shallow, you would initially assist the ventilations at the patient's rate by delivering a ventilation with each breath. Over the next 5–10 ventilations, slowly adjust the rate so that you are ventilating every 5–6 seconds with one of the patient's breaths.

If you are meeting resistance with ventilation in the breathing patient, be sure to first coordinate your ventilation with the patient's spontaneous breaths. Increase or decrease the ventilation rate from that point. Once you have control over the ventilation, the patient may relax and allow you to ventilate with greater ease.

**Continuous Positive Airway Pressure (CPAP)**

Continuous positive airway pressure (CPAP) is a form of noninvasive positive pressure ventilation (NIPPV) used in the awake and spontaneously breathing patient who needs ventilatory support. CPAP is applied typically to patients with respiratory disease or cardiac failure with pulmonary involvement who are in moderate to severe
respiratory distress or early respiratory failure and who have an intact mental status and airway reflex. CPAP applied by the EMT would be delivered via a tight-fitting mask and a specialized CPAP device designed to deliver a continuous flow of air under pressure (Figure 10-37 ■).

**How CPAP Improves Ventilation and Oxygenation**

CPAP is often used to avoid the need to place an endotracheal tube or other advanced airway to artificially ventilate the patient. As already noted, CPAP is delivered via a tightly fitted mask and a device that generates a continuous flow of air through the airways under positive pressure that is higher than normal air pressure. Nasal prongs can also be used to deliver CPAP; however, most EMS systems use a face mask for greater comfort and effectiveness. Oxygen is typically delivered with the positive pressure and could be titrated in response to the SpO2 reading and patient signs and symptoms.

The continuous delivery of air under positive pressure, which is measured in cmH2O, is intended to inflate collapsed alveoli, improve oxygenation, improve pulmonary compliance (allow the lungs to inflate more easily), and reduce the patient’s work of breathing. It takes a great deal of work and energy to reinflate the alveoli with each breath. By keeping the alveoli open with CPAP, less work is required and less energy is used. This typically averts complete respiratory failure or arrest and allows the patient to continue to breathe on his own.

Left ventricular failure increases hydrostatic pressure inside the pulmonary capillaries, forcing fluid out of the capillaries and into the adjoining alveoli, displacing the air in the alveoli and inhibiting gas exchange. The continuous pressure created in the alveoli by CPAP prevents further fluid leakage into the alveoli and actually forces fluid that may already have accumulated out of the alveoli and back into the interstitial space and the capillaries. CPAP improves the heart rate and blood pressure and reduces the sympathetic tone by improving gas exchange and oxygenation. This also decreases afterload and reduces the myocardial workload in an already failing heart.

CPAP is delivered at a continuous airway pressure from 2 cmH2O to 20 cmH2O. Most often, CPAP is initiated at the lowest setting and titrated up to 5 cmH2O. In most protocols, a CPAP pressure of 10 cmH2O is never exceeded because of the increased risk of barotrauma. Some patients may experience improvement with as little as 2 to 2.5 cmH2O. Most orders recommend using a CPAP of 5 cmH2O and titrating upward based on the patient’s physiological response.

**Criteria and Indications for CPAP**

CPAP is used to support ventilations, not as a device to provide artificial ventilation. Patient criteria for CPAP include:

- Awake, alert, and oriented enough to obey commands (GCS >10)
- Able to maintain his own airway
- Able to breathe on his own and has a respiratory rate >25 breaths/minute
- Exhibits signs and symptoms of moderate to severe respiratory distress or early respiratory failure (use of accessory muscles or SpO2 <94%)

The indications for CPAP for the patient in moderate to severe respiratory distress or early respiratory failure, but who is alert and awake enough to obey commands, maintain his own airway, and continue to breathe on his own, include:

- Congestive heart failure
- Pulmonary edema (fluid around and in the alveoli from a high hydrostatic pressure in the pulmonary capillaries)

---

**FIGURE 10-37** CPAP is a form of noninvasive positive pressure ventilation used in the awake and spontaneously breathing patient who needs ventilatory support. (a) CPAP on an adult. (b) CPAP on a child. (Photo a: © Ken Kerr).
• Chronic obstructive pulmonary disease (COPD)
• Asthma
• Pneumonia

**Contraindications for CPAP**

CPAP is contraindicated in patients with:

- Apnea, respiratory arrest, or agonal respirations
- Inability to understand or obey commands (GCS <11)
- Inability to maintain his own airway (associated with an increased risk of vomiting and aspiration)
- Unresponsiveness (associated with an increased risk of vomiting and aspiration)
- Shock associated with cardiac insufficiency (signs of poor perfusion and a SBP <90 mmHg)
- Cardiac arrest
- Actively vomiting (associated with an increased risk of aspiration)
- Upper gastrointestinal bleeding or history of recent gastric surgery
- Pneumothorax or trauma to the chest, especially penetrating trauma
- Tracheotomy
- Facial trauma, especially midface fractures, or facial anomalies
- Increased intrathoracic pressure causing hypotension (SBP <90 mmHg)

CPAP should be used with caution in patients with hypotension and hypovolemia. CPAP creates an increase in intrathoracic pressure that may result in a decrease in cardiac output, worsening the state of hypotension or hypoperfusion.

**CPAP Administration Procedure**

Be sure to completely inform the patient about the CPAP device, how it will feel, and its benefits. It is vital that you continuously coach the patient in order to lessen his anxiety and fear. This is a very difficult procedure for most patients who are struggling to breathe, even though it will improve their condition. Increasing their anxiety will increase their sympathetic nervous system response, increase breathing workload, increase oxygen demand, increase myocardial workload, and worsen their condition. It is imperative that you work into the CPAP quickly, yet slowly enough to allow the patient to become comfortable with the procedure. It may take only 5 to 10 minutes before the patient begins to show improvement.

The detailed procedure for initiating and administering CPAP (EMT Skills 10-6) is as follows:

1. Carefully explain the procedure and the device to the patient. Obtain a set of vital signs and a baseline SpO2 reading. You must do continuous SpO2 monitoring and reassess the vital signs every 5 minutes.

2. Ensure that you have an adequate oxygen source since most CPAP devices use oxygen as their source of pressure. Have a backup tank available, because it is undesirable to discontinue CPAP once it is applied.

3. Place the patient in a seated or semi-Fowler’s position (head and chest at a 45-degree angle).

4. Assemble the breathing circuit to the CPAP device and ensure it is properly functioning.

5. Place the mask over the patient’s nose and mouth and secure it tightly with the straps to limit airflow loss.

6. Increase the CPAP pressure by increments of 2 cmH2O until the patient’s response improves. (See monitoring criteria in the next section.) Most protocols recommend a CPAP of 5 cmH2O. It may be necessary to titrate the pressure to 10 cmH2O in congestive heart failure with pulmonary edema. Do not exceed 10 cmH2O unless directed by medical direction. Check for air leaks and reposition and tighten the mask if necessary once the pressure is applied.

7. Continue to coach the patient. Instruct the patient to breathe in through his nose and exhale slowly through his mouth as long as possible. Some procedures recommend counting aloud to the patient, counting slowly to four during exhalation before allowing him to take another inhalation.

8. Do not discontinue CPAP unless directed by medical direction or after you have arrived at the medical facility and the CPAP has been transferred to their system. If the patient’s level of consciousness deteriorates to a GCS <11 and the patient is no longer able to obey or understand your commands, or if any of the other contraindications arise, immediately remove the patient from the CPAP device. It will then be necessary to continue with an alternative treatment that may include positive pressure ventilation with a bag-valve-mask device.

9. Notify the receiving medical facility that the patient is on CPAP so they can prepare to transfer the patient to their CPAP device upon arrival without discontinuation to the patient.

**Assessing the Patient’s Response to CPAP**

Both physiological (vital signs) and subjective measures can be used to determine the effectiveness of the patient’s response to the CPAP. According to the National Association of EMS Physicians (NAEMSP) resource document on noninvasive positive pressure ventilation (Daily J., Wang H. Noninvasive positive pressure ventilation: resource document for the National Association of EMS Physicians. Prehospital Emergency Care, 2011;15:432-438), the following measures can be used to assess the effectiveness of CPAP.

- **Respiratory rate.** A decrease in the respiratory rate may indicate a positive response to CPAP. However,
if the respiratory rate is decreasing with a decline in the patient’s mental status, it may be an indication that the patient is deteriorating and may need positive pressure ventilation via a bag-valve-mask device.

- **Heart rate.** As the patient’s oxygenation levels improve with CPAP, the heart rate will typically decrease. However, an increase in the heart rate may occur from a rise in intrathoracic pressure with a decrease in venous return, leading to a decline in preload. In this case, to compensate, the heart will increase the rate.

- **Systolic blood pressure.** It is necessary to closely monitor the patient's systolic blood pressure during CPAP. An increase in intrathoracic pressure may cause a decrease in venous return leading to a reduction in preload. As the preload decreases, the systolic blood pressure will also decline. If hypotension (SBP <100 mmHg) or signs of poor perfusion (cyanosis, delayed capillary refill, decreased mental status) become evident, it may be necessary to reduce CPAP pressure or support. If the patient already has a low SBP (<100 mmHg), it may be necessary to consult with medical direction prior to initiating CPAP.

- **Oxygen saturation.** The oxygen saturation in arterial blood should improve with CPAP. The SpO2 reading should continue to improve during treatment. It may be necessary to adjust the CPAP pressure upward to improve the SpO2 reading.

- **End-tidal capnography.** If an end-tidal carbon dioxide (ETCO2) monitor is used during CPAP, the initial response may be an increase in the ETCO2 reading. This results from an improvement in the ventilation-perfusion mismatch, which will increase the elimination of excess carbon dioxide from arterial blood. As the CPAP treatment continues, the ETCO2 reading should decrease, indicating a continuous improvement in gas exchange with effective elimination of the built-up carbon dioxide in the arterial blood.

- **Complaint of dyspnea.** Although a complaint of dyspnea (difficulty breathing) is very subjective, the severity of the patient's complaint should be reduced. In addition, with improvement, a reduction in cyanosis and accessory muscle use should also be seen.

You should continuously monitor the patient for development of a pneumothorax, gastric distention, vomiting, worsening of the respiratory distress or failure, a decrease in mental status, and the patient’s intolerance to the device. If any of these occur, it would be necessary to discontinue the CPAP and select an alternative treatment.

### BiPAP

Bilevel positive airway pressure (BiPAP) is similar to CPAP but allows for different airway pressures to be set for inspiration and expiration. The effectiveness of BiPAP in the prehospital setting has not been adequately studied; therefore, its use in prehospital care is not recommended.

### Hazards of Overventilation

Performing ventilation on patients has many risks. It is often thought that providing more ventilation than that which is necessary might be helpful to the patient. On the contrary, scientific evidence has found that overventilating a patient can lead to serious complications, especially in the cardiac arrest patient and in those with increased pressures in the chest from injury or illnesses.

In the cardiac arrest patient, hyperventilation and prolonged positive pressure ventilation can lead to a decrease in the cardiac output, blood pressure, and perfusion. In one study, it was speculated that higher ventilation rates and volumes increased the pressure inside the chest, not allowing for the development of negative pressure between compressions. The negative pressure between compressions is necessary to draw blood into the chest cavity and increases the blood flow to the right side of the heart. With the pressure in the chest remaining higher than it should be, the amount of blood entering the left side of the heart to be ejected out to the body is severely diminished. This leads to a decrease in the perfusion of both the coronary vessels in the heart and the cerebral vessels in the brain.

When a spontaneously breathing patient is overventilated, where the rate and volume delivered with the ventilation is in excess of the recommended rate and volume, large amounts of air may become trapped in the alveoli, causing the pressure in the chest to remain higher than it should during inhalation and exhalation. The overinflated alveoli may cause the capillaries in the lungs to become compressed and obstruct blood flow to the left atrium. Also, the constant high pressure in the chest would reduce the negative pressure that is able to be generated, thereby reducing the vacuum effect that sucks blood into the right side of the heart with each breath. This would reduce the blood volume that is available to the left ventricle, causing a reduction in cardiac output. This can reduce the blood pressure and perfusion of essential organs such as the brain, heart, lungs, liver, and kidneys.

It is essential to adhere to the recommended ventilation rates and volumes when ventilating a patient, especially the cardiac arrest patient. More ventilation is not good for the patient. What is good for the patient is establishing and maintaining a patent airway, providing good ventilations at the right rate and tidal volume, and providing supplemental oxygen with ventilations.
A Patient with a Stoma or Tracheostomy Tube

A stoma is a surgical opening in the front of the neck that may be permanent or temporary (Figure 10-38a ■). One reason for the presence of a stoma in the patient’s neck is that a tracheostomy has been performed. During a tracheostomy, a stoma is created by cutting through the skin and into the trachea to relieve an obstruction higher in the trachea or to serve in place of an endotracheal tube (a tube through the mouth and into the trachea) that has been in place for a number of hours or days. Often, a tracheostomy tube—a curved hollow tube made of rubber, plastic, or metal—is inserted into the stoma to help hold it open. The patient may be breathing completely through the stoma and tube or may still be getting some air through the mouth and nose, around whatever blockage exists in the trachea. A tracheostomy is usually temporary and will eventually be closed and allowed to heal.

Another reason for the presence of a stoma is a laryngectomy. In a laryngectomy, typically because of cancer, all or part of the patient’s larynx has been removed. In a total laryngectomy, there is no longer any connection of the trachea to the mouth and nose. The trachea is disconnected from the pharynx, brought forward, and connected to the stoma in the neck. This alters the airway so that the patient breathes completely through the stoma. In a partial laryngectomy, some of the tracheal connection to the mouth and nose remains so that the patient may be getting some air through the stoma and some through the mouth and nose (Figure 10-38b ■). With a laryngectomy, the stoma is permanent.

When you encounter a patient with a stoma (with or without a tube in the stoma), it will probably not be immediately obvious whether the patient is able to take in
Bag-Valve-Mask-to-Tracheostomy-Tube Ventilation

The bag-valve device is designed so that it can connect directly to the tracheostomy tube to provide positive pressure ventilation (Figure 10-39 ■). When ventilating through the tracheostomy tube, it may be necessary to seal the patient’s mouth and nose to prevent air from escaping. If this is not done, ineffective ventilation may result, with inadequate tidal volumes delivered to the patient.

If you are unable to ventilate through the tube, first suction it using a soft suction catheter. If you are still unable to ventilate, attempt to ventilate through the mouth and nose while sealing the stoma; this may improve the ability to ventilate or may clear the obstruction preventing ventilation through the tracheostomy tube.

Bag-Valve-Mask-to-Stoma Ventilation

The permanent stoma of a laryngectomy patient is usually at the base of the neck with no tube inserted. Remember that a total laryngectomy patient has no airflow from the mouth and nose, but a partial laryngectomy patient may still have some airflow from the mouth and nose. To perform artificial ventilation with a bag-valve mask to the stoma, follow these guidelines:

1. Remove all coverings (e.g., scarves and ties) from the area of the stoma.
2. Clear the stoma of any foreign matter. Suction the stoma by passing a sterile soft suction catheter through the stoma and into the trachea no more than 3–5 inches. Suction enough to partially open the airway.
3. You will not need to perform a head-tilt, chin-lift or jaw-thrust maneuver on a patient with a stoma. Keep the patient’s head straight and the shoulders slightly elevated.
4. Select a mask, most often a child or infant mask, that fits securely over the stoma and can be sealed against the neck. Hold the mask seal with your hand and squeeze the bag delivering the ventilation over a 2-second period. Watch for adequate chest rise and fall. Feel to be sure that the air is escaping back through the stoma during exhalation.

Mouth-to-Stoma Ventilation

Mouth-to-stoma ventilation is not recommended because it exposes the EMT to respiratory secretions and droplets, causing possible contamination with infectious disease. It is preferable to use a bag-valve-mask device with an infant- or child-sized mask to form a seal over the stoma. Follow the same procedure as for adult ventilation with a bag-valve mask with the exception of forming the mask seal over the stoma instead of over the mouth. If a BVM is not present and you have no other option, you must use a barrier device over the stoma before you perform mouth-to-stoma ventilation.

Infants and Children

Keep the following special considerations in mind when establishing and controlling the airway and providing artificial ventilation in infants and children:

- When establishing an airway by head-tilt, chin-lift maneuver, place the infant’s head in a neutral position without hyperextension. The child’s head should be placed in a neutral position and then only slightly extended. Because of immature development of the airways, hyperextension may actually produce an airway obstruction. Because of the large size of the head, it may be necessary to elevate the upper chest of an infant or small child by placing padding under the shoulders to achieve an adequate airway.

- When providing positive pressure ventilation, regardless of the device or technique used, it is necessary to avoid excessive ventilation volumes and pressures. Excesses in these areas will lead to gastric distention, a common problem while ventilating infants and children. Gastric distention can impede lung inflation, reducing the ventilation volume being delivered, or it can cause the patient to vomit and possibly aspirate the vomitus. Also, excessive volumes can cause lung rupture and injury. The smallest volume that causes the chest to visibly rise is adequate.

- Use a bag-valve-mask device with a minimum volume of 450–500 mL without a pop-off valve. If a pop-off
valve is present, disable it by placing it in a closed or off position. Because of the smaller airways and higher resistance in infants and children, a pop-off valve may unnecessarily vent air and lead to ineffective ventilation.

- Insert an oropharyngeal or nasopharyngeal airway if the airway cannot be maintained with a head-tilt, chin-lift or jaw-thrust maneuver alone or if prolonged ventilation is necessary.
- The ventilation rate for infants and children is 12–20 per minute or one ventilation delivered every 5 to 3 seconds. Be sure the chest rises with each ventilation.

Patients with Facial Injuries

The blood supply to the face is extremely rich; this can lead to two major complications with facial injuries:

1. Blunt injury can cause excessive swelling that may partially or completely occlude the airway. It may be necessary to insert an airway adjunct to establish and maintain the airway. Avoid the use of a nasopharyngeal airway with mid-face trauma. Also, positive pressure ventilation may be needed to force ventilation past the swollen airway.
2. Bleeding into the pharynx may be severe and can cause problems with airway management. Frequent or constant suctioning may be necessary.

Foreign Body Airway Obstruction

You may encounter a responsive or unresponsive patient with a known upper airway foreign body obstruction. It is also possible that an unresponsive patient may have a foreign body obstruction that is only detected after unsuccessful attempts at positive pressure ventilation. In these events, follow the procedure for foreign body airway obstruction to establish a patent airway.

If the patient is responsive and choking but is effectively moving air when inhaling and exhaling, instruct him to cough. Do not perform abdominal thrusts or other foreign body airway obstruction maneuvers. Place the patient on high-concentration oxygen and begin transport. If the breathing becomes weak and ineffective, indicating poor air exchange and severe obstruction, immediately manage the patient as a complete foreign body obstruction. Perform abdominal thrusts in the adult or child, or chest thrusts and back blows (slaps) in the infant. Signs of a severe partial airway obstruction with poor air exchange are:

- Cough that becomes silent
- Stridor heard on inhalation
- Increase in labored breathing

If the patient is 1 year of age or older, perform abdominal thrusts as you would for an adult patient. In an infant who is less than 1 year of age, perform back blows (slaps) and chest thrusts in an attempt to relieve the obstruction.

If the airway is completely occluded and there is no air movement, perform three cycles of the foreign body airway obstruction maneuver. If the obstruction is not relieved, transport the patient expeditiously and continue with the foreign body airway obstruction cycles en route to the hospital until the obstruction is relieved.

Once the obstruction is relieved, closely assess the patient’s breathing status and pulse. If the breathing is inadequate or absent, begin positive pressure ventilation with supplemental oxygen. If no pulse is present, apply the automated external defibrillator (AED) (see Chapter 15, “Shock and Resuscitation”) or, if the AED is not available, begin CPR.

Dental Appliances

If the patient has dentures that are secure in the mouth, leave them in place. It is much easier to establish a tight mask seal with the dentures in place. If the dentures are extremely loose, remove them so they do not dislodge and occlude the airway. Partial dentures (plates) may also become dislodged and occlude the airway. If the partial plate is loose, remove it. Reassess the mouth frequently in patients who have dentures or partial dentures to ensure that these appliances have not come loose.

OXYGEN THERAPY

Oxygen is a colorless, odorless gas normally present in the atmosphere in a concentration of approximately 21 percent. Pure, or 100 percent oxygen is obtained commercially by fractional distillation, a process by which air is liquefied and the gases other than oxygen, primarily nitrogen, are boiled off. Liquid oxygen is then converted under high pressure to a gas and stored in steel or aluminum cylinders under a pressure of about 2,000 pounds per square inch (psi) (Figure 10-40). 

Oxygen Cylinders

A number of different types of oxygen cylinders are available. They vary in size and in the volume of oxygen contained. Even though the volume of oxygen may vary, all of the cylinders when full are at the same pressure, about 2,000 psi. The cylinders are given letter designations according to their size. The following are sizes and related volumes of oxygen cylinders used in emergency medical care:

- D cylinder—350 liters
- E cylinder—625 liters
- M cylinder—3,000 liters
- G cylinder—5,300 liters
- H cylinder—6,900 liters

www.bradybooks.com
**Duration of Flow**

The only way to truly determine the amount of oxygen in the tank is to apply the gauge and identify the psi of pressure remaining in the tank. The pressure remains constant; however, the volume varies based on the size of the tank. Thus, if a D tank had 1,000 psi it would have approximately 175 liters of oxygen remaining (350 ÷ 2 = 175), whereas an M cylinder with 1,000 psi would have approximately 1,500 liters remaining in the tank (3,000 ÷ 2 = 1,500). The M cylinder would allow a much longer oxygen administration period as compared to the D cylinder.

One method to determine the oxygen duration of a tank is to apply some basic numbers to a simple formula (Table 10-7). This is necessary when a patient must be transported for a long period of time while on high-concentration oxygen and you need to determine if the oxygen content of the tank will last the entire time. A nonrebreather mask at 15 lpm uses a significant amount of oxygen. The higher the flow rate, the faster the oxygen is depleted from the tank.

**Safety Precautions**

Because oxygen is a gas that acts as an accelerant for combustion and oxygen cylinders are under high pressure, they must be handled very carefully. Observe the following safety precautions:

- Never allow combustible materials such as oil or grease to touch the cylinder, regulator, fittings, valves, or hoses. Oil and oxygen under pressure will explode if they come into contact. This includes petroleum-based adhesive (adhesive tape) or lubricants such as petroleum jelly.
- Never smoke or allow others to smoke in any area where oxygen cylinders are in use or on standby. Because oxygen makes fires burn more rapidly, it greatly increases the risk of fire, not only from the tank but in towels, sheets, and clothing with which oxygen has come in contact.

**Pressure Regulators**

Gas flow from an oxygen cylinder is controlled by a pressure regulator that reduces the high pressure in the cylinder to a safe range, from 30 to 70 psi, and controls the flow of oxygen from 1 to 15 lpm. These regulators attach to the cylinder by a yoke, a series of...
pens configured to fit cylinders holding only one type of gas. The yoke prevents a regulator from being attached accidentally or purposefully to another type of gas. In addition, all gas cylinders are color-coded according to their contents. Oxygen cylinders in the United States are generally steel green or aluminum gray.

Two types of regulators may be attached to an oxygen cylinder: high-pressure regulators and therapy regulators. The **high-pressure regulator** can provide 50 psi to power a flow-restricted, oxygen-powered ventilation device. It has only one gauge, which registers the cylinder contents, and a threaded outlet. It cannot be used interchangeably with the therapy regulator because it has no mechanism for controlling and adjusting the flow rate. To use the high-pressure regulator, attach the equipment supply line to the threaded outlet and open the cylinder valve fully; then turn it back one-half turn for safety.

The **therapy regulator** can administer oxygen from 0.5 lpm up to 25 lpm. It typically has two gauges, one indicating the pressure in the tank and the other indicating the measured flow of oxygen being delivered to the patient. Some therapy regulators have only one gauge and a dial. The dial shows the tank pressure. The dial, which has lpm markings, is used to select the flow of oxygen to be delivered to the patient. Various oxygen delivery devices require different flow rates.

The pressure in the tank, about 2,000 psi when full, decreases proportionately as the volume of oxygen in the tank decreases. Therefore, a pressure reading of 1,000 psi would indicate that the tank is half full. The pressure in the tank will vary with changes in ambient temperature. An increase in ambient temperature would cause the pressure in the tank to increase, whereas a decrease in ambient temperature would cause a decrease in tank pressure.

**Oxygen Humidifiers**

Oxygen exits the tank in a dry gaseous form. The dryness can be irritating to a patient’s respiratory tract if used over a long period of time. It is possible to add moisture to the oxygen by attaching an **oxygen humidifier** (Figure 10-41) to the regulator. The humidifier, which consists of a container that is filled with sterile water, is connected directly to the regulator. The oxygen device tubing is attached directly to the humidifier. The oxygen leaving the regulator is forced through the water in the humidifier, picking up moisture before exiting and being delivered to the patient. Disposable humidifiers are available for one-time use.

For short periods, it is not harmful to deliver dry oxygen to the patient. Generally, a humidifier is not needed for prehospital administration of oxygen. If oxygen is to be delivered over a long period, as in a transport of an hour or more, a humidifier should be considered. Humidified oxygen is recommended in asthma patients.

### Indications for Oxygen Use

Oxygen is actually a drug. Like other drugs, there are recognized indications for its use:

- Any patient in cardiac arrest or respiratory arrest (100 percent oxygen, or as close to 100 percent as possible, attached to a ventilation device)
- Any patient who is being ventilated via positive pressure ventilation
- Any signs of hypoxia in a patient with an adequate respiratory rate and an adequate tidal volume (amount of air breathed in and out)
- Any patient with an SpO₂ reading less than 94%, depending on the condition
- Medical conditions that may cause hypoxia to cells or organs, such as stroke, heart attack, drug overdose, toxic inhalation, suffocation, foreign body airway obstruction, drowning, asthma attack, allergic reaction, seizures, poisoning, and environmental emergencies where the patient is exhibiting signs and symptoms of hypoxia, shock, or heart failure, or complains of dyspnea
- Any patient with an altered mental status or who is unresponsive
- Injuries to any body cavity or central nervous system component, including head, spine, chest, abdomen, and pelvis
- Multiple fractures and multiple soft tissue injuries
- Severe bleeding that is either external or internal
- Any evidence of hypoperfusion (shock)
- Exposure to toxins (e.g., carbon monoxide, cyanide)

If there is any doubt, it is better to err on the side of benefiting the patient and deliver the oxygen. Never withhold oxygen from a patient who you think may need it.

Should the oxygen be supplied via a mask or nasal cannula—relying on the patient’s own breathing effort to take the oxygen into the body—or should the oxygen be supplied in conjunction with positive pressure...
ventilation to force the oxygen into the patient’s lungs? **Be sure to carefully assess the patient to determine the breathing status prior to making this decision.** It is necessary to determine both that the respiratory rate is adequate and that the tidal volume (amount of air breathed in with each inhalation) is adequate in order to apply oxygen by mask or cannula. If *either* the respiratory rate or the tidal volume is inadequate, immediately begin positive pressure ventilation with oxygen flowing at 15 lpm to the ventilation device.

To assess tidal volume, look at chest rise and fall and listen and feel for air movement from the nose and mouth. If the chest does not appear to be rising and falling adequately or the air movement from the nose and mouth is minimal (shallow breathing), immediately begin positive pressure ventilation. Administration of oxygen by mask or nasal cannula will not provide the tidal volume necessary to get the oxygen to the alveoli for gas exchange. The patient will remain hypoxic and become more hypoxic. Likewise, if the respiratory rate is inadequate, oxygen administration by nasal cannula or mask will not provide an adequate tidal volume nor rate per minute that will reverse or prevent hypoxia. This patient will also need to be ventilated.

Determining whether to ventilate or apply oxygen by a mask or nasal cannula is a critical decision that could alter the outcome for the patient. Always closely assess the patient and be aggressive in management of the airway and ventilation status. Do not withhold ventilation from a patient with inadequate breathing, thinking that the oxygen flowing from an oxygen mask will provide an equal benefit. In many cases, the oxygen provided by mask or cannula will have no benefit, and the patient will continue to deteriorate.

Always err to benefit the patient.

### Hazards of Oxygen Administration

Oxygen administration is clearly indicated in a large number of patients you will be called on to treat. However, oxygen therapy also carries hazards or risks. As mentioned earlier, oxygen is a drug. The following are hazards of oxygen administration:

- **Oxygen toxicity** is a rare event in the prehospital environment. However, if you are called to transport a patient to another facility, it may be necessary to use a low-concentration delivery device for a patient who has been on oxygen for a long period of time. Oxygen toxicity may cause the alveoli in the lungs to collapse, reducing the function of the lungs, and may lead to seizures.

- **Damage to the retina of the eye** through scar tissue formation may occur in premature newborns with excessive oxygen administration. This is not usually a major consideration in the prehospital environment, and oxygen must never be withheld from an infant with any signs of hypoxia or inadequate breathing. However, if you are on a team transporting a premature newborn to another facility, calling for a longer period of oxygen administration, potential oxygen toxicity may be a consideration.

- **Respiratory depression or respiratory arrest** in patients with COPD (emphysema and chronic bronchitis) may occur from administration of high-concentration oxygen. In COPD patients, the body responds to low oxygen levels in the blood as a stimulus to breathe. It was originally thought that raising the oxygen level considerably in such a patient would lead to a quick depression of the respiratory status. (This is unlike a typical person, whose body uses the level of carbon dioxide in the blood, rather than the level of oxygen, to regulate respiration.)

However, it has been discovered that it takes a longer period of time on high-concentration oxygen to “knock out” the COPD patient’s low oxygen drive, known as hypoxic drive, than is normally encountered in the prehospital environment. Thus, never withhold oxygen from a COPD patient who is displaying any signs of hypoxia or who is suffering from respiratory failure or arrest. Again, this may be a consideration in a transport of a patient with a history of COPD from a facility where the patient has been on oxygen for a long period of time. It is usually necessary to deliver lower concentrations of oxygen to this patient, based on the physician’s advice. Monitor the patient closely and be prepared to assist ventilations.

### Clinical Decision Making Regarding Oxygen Administration

In the past, it was never thought that a patient could receive too much oxygen or that the administration of oxygen could be bad. The current thinking represents a dramatic change.

There are conditions such as ischemic stroke, acute coronary syndrome, and post-resuscitation from cardiac arrest in which making too much oxygen available in the arterial blood may increase the damage to the tissue once reperfusion of the ischemic area is achieved. Based on the current research, found in the American Heart Association guidelines of 2010, patients with acute coronary syndrome who are exhibiting evidence of hypoxia or hypoxemia, have a complaint of dyspnea, have signs of heart failure, and have an SpO₂ of ≤94% should receive supplemental oxygen. In these cases, a nasal cannula, not a nonrebreather mask, will be applied, starting with a liter flow of 2 lpm and titrated upward based on the patient’s response to the oxygen therapy.

There is insufficient evidence to support the routine use of oxygen in cases of acute coronary syndrome where the criteria we have just stated for oxygen administration are not met. In the past, it was unheard of not to administer oxygen to a patient with chest discomfort. Now, however, based on the AHA 2010 guidelines, oxygen therapy is no longer a standard treatment. It
is always necessary to follow your local protocols and medical direction.

Similarly, according to the AHA 2010 guidelines, a patient suspected of having an acute ischemic stroke should receive oxygen only if evidence of hypoxemia is present, such as an SpO2 reading of <94% or the presence of cyanosis or if the oxygen saturation is unknown. Even with evidence of hypoxemia, such as an SpO2 reading of <94%, a nasal cannula is applied and 2 to 4 lpm of oxygen is administered. It is no longer deemed appropriate to provide oxygen by a nonrebreather mask at 15 lpm in an attempt to maximize the oxygen concentration in the arterial blood.

It has also been discovered that the improvement of arterial blood oxygenation via the use of a nasal cannula at 2 to 6 lpm is much greater than was thought in the past. The oxygen levels in arterial blood in the patient with adequate perfusion and gas exchange can be increased significantly with the use of a simple nasal cannula at 2 to 6 lpm.

Thus, the decision to administer oxygen, the type of device used, and concentration to be delivered are now clinical decisions made by the EMT. It is important to do so in accordance with your local protocols and with the guidance of medical direction. There are many situations and conditions in which you might decide no oxygen is necessary for the patient. Conversely, there will be situations where you make a clinical decision to apply a nonrebreather mask at 15 lpm and maximize oxygen delivery.

When and When Not to Administer Oxygen

A patient who exhibits any evidence of hypoxia, hypoxemia, or poor perfusion should receive supplemental oxygen. Supplemented oxygen should also be administered if any of the following are present:

- The patient has an SpO2 reading of <94% or the oxygen saturation level is unknown
- The patient complains of dyspnea or exhibits signs of respiratory distress
- Signs of poor perfusion are present (pale, cool, and clammy skin; delayed capillary refill; hypotension; decreased mental status)
- Obvious signs of heart failure
- Suspected shock
- Any situation or condition in which hypoxia or hypoxemia is suspected

Use good clinical decision-making based on the history, physical exam findings, SpO2 reading, and suspicion of the patient’s condition when making a determination to administer oxygen or how much oxygen should be administered. It is no longer acceptable to simply apply a nonrebreather at 15 lpm to every patient. As previously explained, there are cases where this will harm the patient and could worsen his outcome.

There are situations where no oxygen may be necessary. For example, you are assessing a patient who was playing volleyball, landed wrong, and has a suspected fracture to the ankle. He is completely alert and oriented and has no other complaints. His blood pressure, heart rate, and respiratory rate are all within normal limits. His SpO2 is 98% on room air, and he exhibits no signs of hypoxia, hypoxemia, or poor perfusion. You suspect injury other than to the ankle. The correct clinical decision regarding oxygen therapy in this particular patient is not to administer any oxygen.

On the other hand, you arrive on the scene of a motor vehicle crash and find the driver with a suspected fracture to the right tibia/fibula. His blood pressure is 102/88 mmHg, heart rate is 92 bpm, and respiratory rate is 22 breaths/minute. The skin is slightly pale, cool and clammy. The SpO2 is 95% on room air. Because there are obvious signs of poor perfusion (narrow pulse pressure, increased heart rate, increased respiratory rate, and positive skin signs), this patient is suspected of having poor perfusion (shock) and should receive oxygen via a nonrebreather mask with a liter flow of 15 lpm.

With experience, the clinical decision of when or when not to apply oxygen, as well as the device and liter flow, will become easier. As you progress through the following chapters dealing with clinical conditions, suggestions for oxygen administration will be made. However, it is up to you as the EMT to make the correct decision based on your clinical findings for that particular patient. Remember, every patient is different, and it is better to err on the side of caution and administer oxygen if you are unsure. Again, be sure to follow your local protocol and medical direction in regard to oxygen therapy.

Oxygen Administration Procedures

To administer oxygen to a patient, it is necessary to prepare the oxygen tank and regulator. The oxygen system should be full and ready for patient use. However, in some situations, the tank must be changed and the regulator reattached. Follow the guidelines listed next when initiating oxygen administration (EMT Skills 10-7). Before administering oxygen, explain to the patient why the oxygen is needed, how it is to be administered, and how the oxygen delivery device will fit on the patient.

1. Check the cylinder to be sure it contains oxygen. Remove the protective seal on the tank valve.
2. Quickly open, then shut, the cylinder valve for 1 second to remove any dust or debris from the valve assembly.
3. Place the yoke of the therapy regulator over the valve and align the pins. Be sure the regulator washer is present and in the proper place. Hand-tighten the T-screw on the regulator.
4. Slowly open the main cylinder valve about one-half turn to charge the regulator. Check the pressure gauge to be sure an adequate amount of oxygen is available.
5. Attach the oxygen mask or nasal cannula tubing to the nipple of the regulator.
6. Open the flowmeter control. Set the oxygen flow rate at the desired liters per minute.
7. With the oxygen flowing, apply the oxygen mask or nasal cannula to the patient.

Terminating Oxygen Therapy
Follow these steps to terminate oxygen administration:
1. Remove the mask or cannula from the patient.
2. Turn off the oxygen regulator flowmeter control, then turn off the cylinder valve.
3. Open the regulator valve to allow the oxygen trapped in the regulator to escape until the pressure gauge reads zero. Turn the regulator flowmeter control completely off.

Transferring the Oxygen Source: Portable to On-Board
When switching over from a portable oxygen tank to the on-board oxygen source, do not disconnect the oxygen tubing from the regulator while the mask is still on the patient’s face. Instead, remove the mask from the patient’s face before attempting to switch over. The oxygen tubing can easily become caught in sheets, blankets, straps, or other equipment and may require a few minutes to untangle. During this time, if no oxygen is flowing to the mask, the patient’s tidal volume and blood oxygen content will be drastically reduced. Do not inadvertently cause the patient to become hypoxic while switching oxygen sources. Once the oxygen has been reconnected and is flowing, reapply the mask to the patient’s face.

Oxygen Delivery Equipment
A variety of oxygen delivery devices can be used to deliver supplemental oxygen to the patient. The two primary devices used in the prehospital setting are the nonrebreather mask and the nasal cannula. Other devices that you may encounter or use are the simple face mask, partial rebreather mask, Venturi mask, and tracheostomy mask.

Nonrebreather Mask
The preferred method for delivering oxygen in the prehospital setting when a high concentration is desirable is with a nonrebreather mask (Figures 10-42a and 10-42b). This device has an oxygen reservoir bag attached to the mask with a one-way valve between them that prevents the patient’s exhaled air from mixing with the oxygen in the reservoir. The mask also has rubber washers that cover the exhalation ports. This allows air to escape on exhalation but restricts air to flow in the exhalation ports during inhalation. With each inhalation, the patient draws in the contents of the reservoir bag, which is 100 percent oxygen. Because some ambient air is inhaled from around the edges of the mask, the oxygen concentration actually delivered is usually around 90 percent.

The flow from the oxygen cylinder should be set at a rate that prevents the reservoir bag from collapsing when the patient inhales. Most typically, this is 15 lpm. Inflate the reservoir bag completely before applying it to the patient.

ASSESSMENT TIPS
A poorly inflated nonrebreather mask reservoir may cause a decrease in the patient’s tidal volume and worsen the patient’s ventilation and oxygenation status.

Various size nonrebreather masks are available for infants, children, and adults. Select the correct size mask to ensure that maximum oxygen concentration is being delivered.
Most adult patients tolerate the nonrebreather mask well. However, it is restrictive and not tolerated well by infants, children, and some adults. Some patients feel as if they cannot breathe adequately with the device on. You may need to coach the patient to breathe at a normal rate and depth and provide reassurance that he is getting a sufficient amount of oxygen and air. If an infant or small child does not tolerate the mask, either you, a parent, or someone else familiar with the child can hold the mask close to his face, enriching the air he inspires.

**Applying the Nonrebreather Mask.** To apply the nonrebreather mask:

1. Explain to the patient that you are going to apply oxygen through a mask. Reassure him that he will be getting an increased amount of oxygen and instruct him to breathe normally.

2. Select the appropriate-sized mask. Prepare the oxygen tank and set the regulator at 15 lpm. Connect the nonrebreather tubing to the regulator. Fill the reservoir bag completely. You may need to press down on the rubber valve gasket found covering the one-way valve between the mask and the reservoir. This will cause the reservoir bag to fill much faster.

3. Once the reservoir is completely inflated, fit the mask to the patient’s face. Bring the elastic strap around the back of the head and secure it. Form the soft metal piece at the top of the mask to conform with the nose.

4. Constantly monitor the reservoir bag to ensure that it remains filled during inhalation.

**Nasal Cannula**

An alternative oxygen delivery device is a nasal cannula. It provides a very limited oxygen concentration ranging from approximately 24 to 44 percent. The main indication for its use is a patient who is not able to tolerate a nonrebreather mask, despite coaching and reassurance from the EMT, and a patient who requires a low concentration of supplemental oxygen.

The nasal cannula consists of two soft plastic tips, commonly referred to as nasal prongs, that are connected by thin tubing to the main oxygen source (Figures 10-43a and 10-43b). The nasal prongs are inserted a short distance into the nostrils. The nasal cannula is a “low-flow” system that does not supply enough oxygen to provide the entire tidal volume during inspiration. Therefore, a large portion of the patient’s inhalation consists of ambient air that is mixed with the oxygen supplied by the nasal cannula. This significantly reduces the concentration of oxygen delivered by the device. As a general rule, for every liter per minute of flow delivered, the oxygen concentration the patient inhales increases by 4 percent. The liter flow for the nasal cannula should be set at no less than 1 lpm and no greater than 6 lpm. Thus, the delivered oxygen concentration ranges from 24 to 44 percent.

**Applying the Nasal Cannula.** Follow these procedures when using the nasal cannula:

1. Explain to the patient that the oxygen will be delivered through the prongs that will fit in each nostril. Instruct the patient to breathe normally while the prongs are in place.

2. Prepare the oxygen tank and regulator. Connect the nasal cannula tubing to the regulator and set the liter flow between 4 and 6 lpm or according to your local protocol or medical direction.

3. Insert the two prongs of the cannula into the patient’s nostrils with the tab facing down. Make sure that the prongs curve downward.

4. Position the tubing over and behind each ear. Gently secure it by sliding the adjuster underneath the chin. Do not make the tubing too tight. If an elastic strap is used, adjust it so it is secure and comfortable.

5. Check the cannula position periodically to ensure that it has not dislodged.
Other Oxygen Delivery Devices

The following devices are also used to deliver oxygen to the patient.

**Simple Face Mask.** A simple face mask has no reservoir and can deliver up to 60 percent oxygen, depending on the patient’s tidal volume and the oxygen flow rate (Figure 10-44). Exhaled air exits through the holes on each side of the mask. Air is drawn in through the holes in the side of the mask, diluting the oxygen concentration being delivered. The oxygen flow rate is usually set at 10 lpm but must not be set at less than 6 lpm. Because it does not deliver as high a concentration of oxygen as the nonrebreather mask, it is not recommended for prehospital use.

**Partial Rebreather Mask.** The partial rebreather mask looks very similar to the nonrebreather mask but is equipped with a two-way valve that allows the patient to rebreathe about one-third of his exhaled air (Figure 10-45). Since the initial portion of exhaled air is principally from the patient’s dead space, areas of the respiratory system where gas exchange does not occur, it contains mostly oxygen-enriched air from the previous inhalation. The flow rate is typically set at 10 lpm but should be no less than 6 lpm. Partial rebreather masks can provide oxygen concentrations of between 35 and 60 percent.

**Venturi Mask.** The Venturi mask is a low-flow oxygen system that provides precise concentrations of oxygen through an entrainment valve connected to the face mask (Figure 10-46). The entrainment valve can be changed to deliver precise oxygen concentrations at preset flow rates. This mask is commonly used for a patient with a history of COPD because of its ability to deliver a precise concentration of oxygen.

**Tracheostomy Mask.** The tracheostomy mask is used to deliver aerosolized medication, bland aerosol therapy, or oxygen to a patient with a tracheostomy tube (Figure 10-47). A T-tube is commonly used for this purpose; however, the tracheostomy mask is preferred. The advantages of the tracheostomy mask are the following: (1) there is less traction on the airway from pulling associated with the T-tube, and (2) secretions can escape from the tube. The main disadvantage is that the tracheostomy mask will deliver only lower concentrations of oxygen, typically less than 50 percent. If lower oxygen levels can be tolerated by the patient, the tracheostomy mask is the preferred device.
**EMT SKILLS 10-1**

**Suctioning Technique**

1. **10-1A** Make sure the suction unit is properly assembled.
2. **10-1B** Measure the catheter from the corner of the mouth to the earlobe.
3. **10-1C** Open the patient’s mouth and insert the catheter.
4. **10-1D** Apply suction as you withdraw the catheter.

**EMT SKILLS 10-2**

**Inserting an Oropharyngeal Airway**

1. **10-2A** Measure to ensure correct size.
2. **10-2B** Insert with tip pointing up toward roof of mouth.
Inserting a Nasopharyngeal Airway

- 10-2C  Advance while rotating 180°.
- 10-2D  Continue until flange rests on the teeth.

- 10-3A  Measuring the nasopharyngeal airway.
- 10-3B  Lubricate it with water-soluble lubricant.
- 10-3C  Insert with the bevel toward the septum or base of the tonsil.
Patient Has Breathing Difficulty: When and How to Intervene

- **10-4A** The patient is breathing normally but has an underlying condition that requires oxygen.
- **10-4B** The patient is suffering mild respiratory distress but still breathing with an adequate rate and tidal volume.
- **10-4C** The EMT places a nonrebreather mask on the patient and administers high-concentration oxygen.
- **10-4D** The patient is suffering respiratory failure with rapid ventilations and inadequate tidal volume.
- **10-4E** The EMTs administer positive pressure ventilation.
- **10-4F** The patient is in severe respiratory failure with completely inadequate respirations.
- **10-4G** The EMTs administer positive pressure ventilation.
EMT SKILLS 10-5

In-Line Stabilization During Bag-Valve Ventilation

■ **10-5A** Technique for one EMT to maintain in-line stabilization while performing one-person bag-valve-mask ventilation.

■ **10-5B** Technique for two EMTs to maintain in-line stabilization while performing bag-valve-mask ventilation.

■ **10-5C** Alternative technique for two EMTs to maintain in-line stabilization while performing bag-valve-mask ventilation.
**EMT SKILLS 10-6**

**Continuous Positive Airway Pressure (CPAP) Procedure**

- **10-6A** Assess vital signs and obtain an SpO2 reading. Carefully explain the procedure and device to the patient. Assemble the equipment.

- **10-6B** Place the mask over the patient’s nose and mouth and secure it tightly with the straps.

- **10-6C** Increase and set CPAP pressure according to your local protocol.

- **10-6D** Continue to coach the patient to breathe in through his nose and to exhale slowly through his mouth as long as possible.

**EMT SKILLS 10-7**

**Initiating Oxygen Administration**

- **10-7A** Identify the cylinder as oxygen and remove the protective seal.

- **10-7B** Crack the main cylinder for 1 second to remove dust and debris.
**10-7C** Place the yoke of the regulator over the cylinder valve and align the pins.

**10-7D** Hand-tighten the T-screw on the regulator.

**10-7E** Open the main cylinder valve to check the pressure.

**10-7F** Attach the oxygen delivery device to the regulator.

**10-7G** Adjust the flowmeter to the appropriate liter flow.

**10-7H** Apply an oxygen device to the patient.
Chapter Review

SUMMARY

Without an adequate airway, oxygenation, or ventilation, all other emergency care provided to the patient will be futile. The most basic and fundamental care provided to all patients focuses on establishing and maintaining a patent airway and providing adequate ventilation and oxygenation. A foundation of knowledge of airway and respiratory anatomy and physiology will help you achieve a better understanding of the signs and symptoms and the emergency care related to these systems.

Assessment of the airway, oxygenation, and ventilation status occurs very early in your patient contact. Each of these is a separate and distinct component. Assessing or managing one component—airway, oxygenation, or ventilation—does not necessarily mean that the other components will be assessed or managed effectively. As an example, a patient can have an open airway but ineffective ventilation, or adequate ventilation but ineffective oxygenation. Thus, it is imperative to become highly efficient in the assessment of all three components and remain vigilant of any changes in their status.

A closed airway is opened using either the head-tilt, chin-lift maneuver or the jaw-thrust maneuver. The head-tilt, chin-lift maneuver is performed on patients who do not have any suspected spinal injury, whereas the jaw-thrust maneuver is used to open the airway in a patient who has a suspected spinal injury while maintaining manual in-line spinal stabilization. Airway adjuncts can be used to assist in establishing and maintaining an airway. The oropharyngeal airway can be inserted only in patients who have no gag reflex. The nasopharyngeal airway can be used in patients who still have a slight gag reflex. Suctioning may be needed to clear an airway of blood, vomitus, secretions, or other obstructions.

Once the airway is established, the ventilation status is assessed. If the patient has inadequate breathing, he must be immediately ventilated using a pocket mask, bag-valve-mask device, or flow-restricted, oxygen-powered ventilation device. Some systems use automatic transport ventilators once the need for prolonged ventilation has been established.

Oxygen therapy is used to reduce, eliminate, or prevent hypoxia from occurring in the patient. The oxygen status is often assessed through the use of a pulse oximeter. Oxygen may be delivered through the ventilation device or by a non-rebreather mask or nasal cannula. The non-rebreather mask delivers the highest concentration of oxygen, and thus it is the preferred device for EMTs in the prehospital setting.

When assessing and managing the airway, ventilation, and oxygenation, you must also be aware of special circumstances or patient conditions that may provide challenges, such as a patient with a stoma or tracheostomy tube, infants and children, facial injuries, foreign body obstruction, and dental appliances.

Case Study Follow-up

Scene Size-up

You and your partner have been dispatched to the Twilight Bar for an unresponsive male patient. Because the bar is frequently the site of fights, stabbings, and shootings, you approach the scene cautiously. You contact dispatch to inquire as to whether the unresponsive patient was involved in some type of altercation. Dispatch informs you that the patient is thought to be unresponsive because of drinking heavily.

As you enter the bar, it is dark and hard to see. You turn on your flashlight and weave your way around the patrons, tables, and bar stools. You continuously scan the scene for any indication of hazards to you and your partner. You finally make your way to the bar and ask the bartender, “Where is the unresponsive patient?” The bartender says, “Oh, he’s in the john.” You ask what happened. He replies, “This kid was in here drinking all morning and afternoon. He stumbled to the bathroom. One of the other guys found him passed out in there.”

You proceed to the bathroom and cautiously open the door, continuously scanning the scene for any signs of a hazard. You find a male patient about 30 years of age on the floor lying in a puddle of vomit. The scene does not reveal any overt signs of a mechanism of injury, but you are still unsure why the patient is unresponsive. No one at the scene knows his name or has ever seen him before.

Patient Assessment

You instruct your partner to take in-line stabilization. You quickly inspect and palpate the back, and on the count of three, you log roll the patient into a supine position on a backboard. You immediately suction the remaining vomitus out of the mouth and then perform a jaw-thrust maneuver. The patient is not responsive, even to a painful pinch, and has no gag reflex, so you are able to insert an oropharyngeal airway without incident.

The breathing rate is approximately 6 per minute with minimal chest rise on inspiration. The breathing rate and tidal volume is inadequate, so you begin positive pressure ventilation with a bag-valve mask and supplemental oxygen at a rate of 10 ventilations per minute by delivering a ventilation every 6 seconds. There are only two of
you to work on the patient, so your partner holds in-line stabilization with her knees and thighs, maintains the jaw thrust and seals the mask to the patient’s face with one hand, and squeezes the bag against her side with the other. While she is doing this, you call for a backup and continue with the primary assessment, which reveals a radial pulse that is slow and weak at a rate of about 55 per minute. The skin is pale, cool, and cyanotic. Because the patient is unresponsive and has no gag reflex, he is considered a priority for transport.

Your partner maintains in-line stabilization and continues to ventilate the patient. You quickly begin a physical exam to check the patient’s body, starting at the head, for any evidence of injury. There are no signs of trauma to the head or neck. You palpate the posterior cervical region and apply a cervical spinal immobilization collar. You continue by checking the chest, abdomen, pelvis, and extremities (having checked the posterior body) and find no signs of trauma. You obtain a set of baseline vital signs.

Since the patient is unresponsive and there were no witnesses, except the bartender who reported his prolonged drinking, there is no way to get any additional history on the patient.

As you are completing the vital signs, your backup crew arrives, bringing in the stretcher. You completely immobilize the patient to the backboard. One newly arrived EMT establishes a seal on the bag-valve mask and your partner begins two-handed ventilation. You move the patient into the ambulance and begin transport.

En route to the hospital, you pinch the patient’s hand and there is still no response. You interrupt ventilation for about 2 seconds to ensure that the airway is clear of vomitus and secretions. Ventilation is continued and the oxygen source is switched over to the on-board tank. You take another set of vital signs and continue with ventilation, monitoring the airway and breathing.

The patient begins to vomit, and you immediately begin to suction as your partner and the other EMT tilt the board, with the patient firmly secured to it, up on its side to help drain the vomitus from the mouth. Once the vomitus is cleared, you continue ventilation. You record the vitals and contact the hospital.

Upon arrival at the hospital, you help transfer the patient to the hospital bed. You report your assessment findings and emergency care to the physician. Once your prehospital care report is completed and the unit is cleaned and restocked, you clear and mark back into service.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.

### IN REVIEW

1. Describe the two manual methods used to open an airway, and explain the circumstances in which each should be used.
2. Name the two airway adjuncts that can be inserted to assist in establishing and maintaining an open airway, and explain the circumstances in which each should be used.
3. Outline the assessment techniques you would use to determine if the patient’s breathing is adequate or inadequate.
4. Name the signs of adequate breathing.
5. Name the signs of inadequate breathing.
6. Name the recommended methods that the EMT can use to artificially ventilate the patient.
7. Explain the difference in the technique for ventilation of a patient with and without a suspected spinal injury.
8. List the indications that the patient is being ventilated adequately.
9. Describe the appropriate procedure for initiating oxygen administration.
10. Describe the appropriate procedure for terminating oxygen administration.

### CRITICAL THINKING

You arrive on the scene and find a 67-year-old male patient lying supine on the couch in the living room. The family states the patient began complaining of a sudden onset of an extremely severe headache, and then he appeared to be confused and losing consciousness. They laid him on the couch to prevent further injury. The patient is not alert and exhibits flexion posturing when a trapezius pinch is applied. You hear snoring sounds with inhalation and exhalation. His chest is moving minimally with each breath and his respirations are approximately 5–6 per minute. His radial pulse is strong. His heart rate is approximately 50 per minute. His skin is normal color, warm, and dry. Your partner applied a pulse oximeter and it reads 79%.

1. What is the status of the patient’s airway?
2. How would you manage the airway in this particular patient?
3. What is the status of his ventilation?
4. What intervention would you provide to manage the ventilation?
5. What is the oxygenation status of the patient?
6. What intervention would you provide to manage the oxygenation status?
PART 6  Assessment

COMPONENTS OF THE PATIENT ASSESSMENT: AN OVERVIEW

During an emergency call, you will perform certain procedures, known as patient assessment, to find out what is wrong with the patient to help you decide what emergency medical care should be provided and how quickly the patient needs to be transported to a medical facility. As the EMT at the scene, you also become the eyes and ears of all emergency care personnel, since you will have access to the home or other emergency scene and to family and bystanders who will not be available to other health care providers, especially those at the hospital emergency department to whom you will transfer the care of your patient.

Always remember that each patient’s condition is unique—even though the patient may have the same signs and symptoms as another patient you treated previously. It is easy to develop tunnel vision and focus on the patient’s chief complaint (the reason that EMS was called), especially if the complaint is dramatic, while failing to determine the entire extent of the patient’s condition.

For example, if you find an elderly man lying on the living room floor complaining of excruciating pain to his hip with obvious deformity, you would quickly conclude that the patient must have fallen and injured his hip. Immediate immobilization of the hip, followed by transport to the hospital, might then seem to be the most appropriate care for this patient.

However, it is vital that you question the patient to determine the cause of the fall. If the patient says he fell after tripping on the rug, the apparent hip injury is your primary concern. But suppose the patient tells you he fell because, while crossing the room, he began to suffer severe chest pain and dizziness. You realize that the patient’s fall was probably caused by a medical condition, possibly a heart attack. Now your focus has changed. You will deal first with the medical condition, which is potentially more serious than the hip injury. The hip injury, though significant, becomes a secondary priority.

So, you can see that it is necessary to perform a complete assessment on every patient. Immediately focusing in on whatever is obvious or dramatic will often cause the EMT to miss injuries or conditions that are important, even potentially life threatening. No matter how significant—or insignificant—the most obvious complaint or injury may seem, you must be suspicious that other injuries or medical conditions exist that you have not yet found.

Throughout the patient assessment, respect the patient’s feelings. Protect his dignity and modesty, explain what you are doing, and—without being dishonest—reassure him that everything is being done to help him.

For a detailed overview of the components of patient assessment and how they apply to different kinds of patients, see the flowchart on the next page. Return to this chart as you read through this module to track the steps of patient assessment you are learning about.

COMPONENTS OF PATIENT ASSESSMENT

- Scene size-up
- Primary assessment
- Secondary assessment
- Reassessment

The purposes of patient assessment are described below with, in brackets, the step(s) when each would primarily be accomplished.

- To determine whether the patient is injured or has a medical illness [scene size-up; primary assessment]
- To identify and manage immediately life-threatening injuries or conditions [primary assessment; as appropriate during secondary assessment]
- To determine priorities for further assessment and care on the scene vs. immediate transport with assessment and care continuing en route [primary assessment; as appropriate, throughout the assessment]
- To further examine the patient and gather a patient history [secondary assessment]
- To provide further emergency care based on additional findings [secondary assessment]
- To monitor the patient’s condition, assessing the effectiveness of the care that has been provided and adjusting care as needed [reassessment, until the patient is transferred to the receiving facility]
Patient Assessment Flowchart

Scene Size-up
- Safe Scene
- Unsafe Scene

Primary Assessment
- TRAUMA PATIENT
  - Secondary Assessment
    - Evaluate Mechanism of Injury, Mental Status
      - Significant MOI, Altered Mental Status, or Suspect Multiple Injuries
        - Rapid Secondary Assessment
          - Baseline Vital Signs
            - History
              - Transport
          - History
          - Transport
      - No Significant MOI, Alert and Oriented
        - Modified Secondary Assessment for Specific Injury
          - Baseline Vital Signs
            - History
              - Transport

Baseline Vital Signs, Monitoring Devices, and History Taking

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Assessment** (Content Areas: Secondary Assessment; Monitoring Devices; History Taking)

**COMPETENCY •** Applies scene information and patient assessment findings (scene size-up, primary and secondary assessment, patient history, and reassessment) to guide emergency management.

**OBJECTIVES •** After reading this chapter, you should be able to:

11-1. Define key terms introduced in this chapter.
11-2. Explain the importance of taking and recording a patient's vital signs over a period of time to identify problems and changes in the patient's condition and of accurately documenting the vital signs and patient history.
11-3. Perform the steps required to assess the patient's breathing, pulse, skin, pupils, blood pressure, and oxygen saturation and consider the patient's overall presentation when interpreting the meaning of vital sign findings.
11-4. Differentiate between normal and abnormal findings when assessing a patient's breathing, to include the respiratory rate, quality of respirations, rhythm of respirations, and signs that may indicate respiratory distress or respiratory failure.
11-5. Differentiate between normal respiratory rates for adults, children, infants, and newborns and evaluate the need to administer treatment based on assessment of a patient's breathing.
11-6. Auscultate breath sounds to determine the presence of breath sounds, equality of breath sounds, and the presence and likely underlying causes of abnormal breath sounds.
11-7. Assess the pulse at various pulse points and consider the patient's age and level of responsiveness when selecting a site to palpate the pulse.
11-8. Differentiate between normal and abnormal findings when assessing a patient's pulse, to include the pulse rate, quality of the pulse, and rhythm of the pulse.
11-9. Associate pulse abnormalities with possible underlying causes and describe the changes in the pulse associated with pulsus paradoxus.
11-10. Recognize normal and abnormal findings in the assessment of skin color, temperature, condition, capillary refill, and color of the mucous membranes and associate abnormal skin findings with potential underlying causes.
11-11. Explain factors that can affect capillary refill findings.
11-12. When assessing the pupils, recognize dilation, constriction, inequality, and abnormal reactivity and associate abnormal findings with potential underlying causes.
11-13. In relation to blood pressure measurement, explain systolic and diastolic blood pressure, consider normal values for age and gender, find the pulse pressure, and identify potential causes of abnormal findings or changes.
11-14. Compare palpation and auscultation of blood pressure as to processes, useful findings, and documentation and discuss how technique and selection of equipment can affect the accuracy of readings.
11-16. Given a patient scenario, determine the frequency with which vital signs should be reassessed.
11-17. Explain what pulse oximetry measures, use pulse oximetry to help determine the need for supplemental oxygen, and describe factors and limitations in interpreting pulse oximetry findings.
11-18. Describe the correct procedure for noninvasive blood pressure monitoring.
11-19. Describe the processes for controlling the scene, achieving a smooth transition of care, and reducing the patient's anxiety.
11-20. Determine a patient's chief complaint.
11-21. Given a scenario, efficiently elicit an adequate patient history using closed-ended and open-ended questions and active listening techniques.
11-22. Use the mnemonics SAMPLE and OPQRST to ensure a complete prehospital patient history.
11-23. React appropriately when asking questions about sensitive topics or when caring for patients who present special challenges to history-taking and assessment.
INTRODUCTION

Accurate measurement and recording of vital signs over a period of time may reveal critical trends in the patient’s condition. The patient history is just as important. It can guide your pace, shine a light on underlying problems, and—if the patient loses consciousness—can be the only source of information important for hospital personnel to know.

As an EMT, you will perform a variety of skills necessary to manage a patient’s injuries or illness. There is one skill, however, that you will perform on every patient—one skill that is the basis for all the emergency care you will provide. That skill is patient assessment. Like putting together the pieces of a puzzle, the EMT uses each detail revealed by the assessment to help build a picture of the patient’s condition and to make informed decisions on emergency care.

Among the fundamental pieces of information you will gather during your assessment of each patient are the patient’s vital signs and the patient’s history. Monitoring equipment will be used to gather additional assessment information not obtainable in the traditional physical exam, such as the amount of glucose in the blood or amount of hemoglobin saturated with oxygen.

GATHERING PATIENT INFORMATION

When you arrive at the scene of an emergency call, you will need to find out all you can about the patient’s condition: What’s wrong with the patient right now? What led up to the problem? and so on. The process of finding out is called assessment. Most of your EMT course and most of the chapters of this text are devoted to teaching you how to assess, as well as how to care for, a patient in the prehospital setting.

Much of the information you gain during assessment is readily obvious or available. An open bottle of bleach may provide the clue to a poisoning. The patient or a family member may tell you the chief complaint—for example, “I can’t catch my breath,” or “I hurt my leg...
when I fell.” The fact that the patient is answering questions clearly may tell you that he is alert, has an open airway, is breathing adequately, and has a pulse. As you conduct a physical exam, you may spot swelling, cuts, bruises, or other signs of injury.

Other indications of the patient’s condition require a bit of “detective work”—some special skills for finding out more than what is readily obvious. These skills include measuring the patient’s vital signs and asking questions to obtain the patient’s history.

Always be aware of the feelings, such as anxiety or embarrassment, that a patient may experience during assessment. Continually reassure the patient and respect his dignity.

### BASELINE VITAL SIGNS

You can’t get inside the patient’s body to see what is going on, but you can measure the **vital signs**. These are the “signs of life”—outward signs that give clues to what is happening inside the body. The vital signs that you will measure are:

- Respiration
- Pulse
- Skin
- Pupils
- Blood pressure
- Pulse oximetry

Correctly reading and interpreting the vital signs significantly affects the success of prehospital emergency care as well as providing critical information for the hospital staff. Taking two or more sets of vital signs and comparing them will reveal changes in the patient’s condition and may indicate how effectively you are managing the patient’s injury or illness, or if the patient is deteriorating. The first set of measurements you take are known as the **baseline vital signs**, to which subsequent measurements can be compared. It is important to look for trends in the vital sign readings. As an example, a blood pressure that continues to decrease and a heart rate that continues to increase would be significant findings in a patient who is losing blood.

Although you can monitor most of the vital signs with your senses (looking, listening, feeling), it is necessary that you use and routinely carry the following equipment:

- A **sphygmomanometer** (blood pressure cuff) in adult and pediatric sizes to measure blood pressure
- A stethoscope to take blood pressure and listen to lung sounds
- A wristwatch that counts seconds to measure pulse and respiratory rates
- A penlight to examine pupils
- A pair of EMT shears for cutting away clothing
- A pen and pocket notebook for recording vital signs and other findings

- Your personal protective equipment for Standard Precautions, such as protective gloves, eyewear, and face mask
- Pulse oximeter to establish and monitor the oxygen saturation in the blood

### Respiration

#### Respiratory Rate

The respiratory rate is assessed by observing the patient’s chest rise and fall (Figure 11-1). The normal respiratory rate range for an adult patient at rest is 8 to 24 per minute. On average, the range falls between 12 and 20 breaths per minute. Typically, respiratory rates that are less than 8 or greater than 24 are of concern. First, however, look at the patient and determine if he looks to be in respiratory distress; second, assess his mental status and pay attention to his speech pattern. For example, if you encounter a patient with a respiratory rate of 8 who is alert, oriented, and able to answer your questions without gasping for a breath or showing a struggle to breathe, 8 may be his normal respiratory rate, and no intervention is necessary. On the other hand, if the patient has his eyes closed, needs to be aroused with verbal stimuli, appears fatigued, appears to be struggling to breathe, or speaks only a couple of words before gasping for a breath, you would consider ventilating the patient.

Look at the respiratory rate in relation to the presentation of the patient. Do not be misled by a respiratory rate that falls within the normal limit and consider it “normal” when the patient’s clinical signs tell you otherwise. Base your determination of “normal” on the patient’s presentation and not on a predetermined “normal” range. What may be normal for one patient may be abnormal for another.

Keep in mind that the resting respiratory rate of the elderly is typically higher, with an average of 20 breaths per minute. Elderly patients have a decreased tidal volume. As a consequence, they must make up the deficit in the volume they breathe by increasing the respiratory rate.
rate. A respiratory rate of 22 in an 18-year-old may be alarming, but the same rate of 22 in an elderly person may be considered normal.

Any adult patient breathing at a rate greater than 40 per minute or an infant or young child breathing greater than 60 per minute should be ventilated for two reasons: (1) The patient will not be able to sustain that rate for a long period because of the increase in workload to breathe and the respiratory muscle fatigue that will follow, and (2) the rate is so fast the lungs don’t have time to fill adequately, leading to a drastic reduction in tidal volume. General ranges for respirations per minute are (see also Table 11-1):

- Adults—8–24 per minute
- Adolescents—12–20 per minute
- Children—15–30 per minute
- Infants—20–40 per minute
- Newborns—30–60 per minute

Respiratory rate—the number of respirations per minute—is usually determined by counting the number of breaths in a 30-second period and multiplying by 2. (One breath = one inhalation + one exhalation.) If the patient knows you are counting, it can influence the rate. Instead, you can pretend you are checking the radial pulse and cross the patient’s arm over the lower chest while actually counting respirations.

**PATHOPHYSIOLOGY PEARLS**

Pain will trigger the sympathetic nervous system, causing an increase in the respiratory rate. As the pain is reduced, the respiratory rate will decrease.

**Respiratory Quality**

Determining quality of respiration, or breathing, is as important as determining rate. It will tell you the volume of air moving in and out of the lungs with each breath, the volume per minute, and how well it is moving. The quality of respiration is an assessment of tidal volume. If either the respiratory rate or the tidal volume is found to be inadequate, then the patient’s respiratory status is inadequate and positive pressure ventilation must be initiated. The quality of breathing may be normal or abnormal. A normal quality correlates with an adequate tidal volume, whereas an abnormal quality is usually an indication of an inadequate tidal volume. An abnormal quality of breathing may be shallow, labored, or noisy. You can assess the quality of respiration while you are counting the rate.

- **Normal respiration** involves average chest wall motion, which is at least 1 inch of expansion in an outward direction. The patient does not use the accessory muscles of the chest, neck, or abdomen while breathing. Rate is normal, and inhalations are neither prolonged nor excessively short. Exhalation is typically twice as long as inhalation. Normal breathing is quiet; it does not produce abnormal sounds or noises.
- **Shallow respiration** is indicated by only slight chest or abdominal wall expansion upon inhalation. This typically indicates an inadequate tidal volume and requires positive pressure ventilation.
- **Labored respiration**, where the patient is working hard to breathe, is indicated by an abnormal sound of breathing that may include grunting or stridor (a harsh, high-pitched sound); the use of accessory muscles in the neck, chest, or abdomen breathe; nasal flaring; and sometimes gasping. In infants and children, there may be retraction of the skin, muscles, and other tissues around the clavicle and between the ribs. The use of accessory muscles in the neck and chest usually indicates that the patient is struggling to inhale, whereas excessive abdominal muscle use is usually an indication of trouble exhaling. The use of accessory muscles requires an increase in the amount of energy expended to breathe. This may lead to respiratory muscle fatigue and a failure in the ability of the patient to breathe adequately.
- **Noisy respiration**, or an abnormal sound of breathing (Table 11-2), may include snoring, wheezing, gurgling, crowing, or stridor. Auscultate the chest with a stethoscope to determine if breath sounds are present on both sides and to identify any noisy breathing sounds not audible to the ear alone. In the trauma patient you will auscultate the lungs primarily to determine if breath sounds are present or absent, whereas in the medical patient you are more focused on abnormal breath sounds. Sounds heard during auscultation may include wheezing, rhonchi, and crackles (rales).

Remember to record your observations.

**Respiratory Rhythm**

The respiratory rhythm—the regularity or irregularity of respirations—can be easily affected by speech, activity, emotions, and other factors in the conscious and alert patient. However, an abnormal respiratory rhythm—that is, an irregular pattern of respiration—in the patient with an altered mental status is a serious concern. It may indicate
A radial pulse should be assessed in all patients 1 year or older (Figure 11-2). In patients younger than 1 year the neck is short and stubby, making it difficult to locate the carotid pulse; thus, assess a brachial pulse (Figures 11-3a and 11-3b). When a peripheral pulse

...a medical illness, a chemical imbalance, or brain injury. It is important to assess for adequacy of respiration by assessing the rate and tidal volume when faced with an irregular respiratory pattern. Intervene by ventilating, if necessary, and document and report your findings.

**Pulse**

**Location of Pulses**

As mentioned in Chapter 7, the pulse is the pressure wave generated by the contraction of the left ventricle. The pulse directly reflects the rhythm, rate, and relative strength of the contraction of the heart as well as the volume of blood being pumped out of the heart, and it can be felt at any point where an artery crosses over a bone near the surface of the skin. Central pulses (carotid and femoral) and peripheral pulses (radial, brachial, posterior tibial, and dorsalis pedis) can be felt at the following locations:

- **Carotid artery**, on either side of the neck in the groove between the trachea and the muscle mass
- **Femoral artery**, in the crease between the lower abdomen and the upper thigh (groin)
- **Radial artery**, proximal to the thumb on the palmar surface of the wrist
- **Brachial artery**, on the medial aspect of the arm, midway between the shoulder and the elbow between the biceps and triceps muscles
- **Popliteal artery**, in the crease behind the knee
- **Posterior tibial artery**, behind the medial malleolus (ankle bone)
- **Dorsalis pedis artery**, on the top of the foot on the great-toe side
cannot be obtained in patients older than 1 year of age, assess the carotid pulse (Figures 11-4a and 11-4b ■). When palpating the carotid pulse, take care not to compress too hard, which may impede circulation to the brain. Never assess the carotid pulse on both sides at the same time, and avoid excessive pressure in elderly patients.

**Assessment Tips**

If the patient is unresponsive, assess the carotid (central) and the radial (peripheral) pulse at the same time so that there is no delay in determining if a pulse is truly present. This also provides a quick assessment of the patient’s perfusion status.

**Pulse Rate**

A pulse rate (Table 11-3) should be taken as soon as possible and frequently. The average resting rate range is 60–80 beats per minute (bpm) for an adult, 60–105 for an adolescent, 60–120 for a school-age child, 80–150 for a preschooler, 120–150 for an infant, and 100–180 for a newborn. In the adult patient, a heart rate greater than 100 bpm is termed **tachycardia** and a heart rate less than 60 bpm is called **bradycardia**.

Like respirations, the heart rate must be considered in relation to the patient’s presentation and assessment findings. A heart rate that falls within the limits of 60 to 100 bpm could be considered abnormal for some patients, whereas a heart rate falling outside of these limits could be considered normal. As an example, a resting heart rate of 42 bpm is obtained for a 34-year-old male patient who injured his ankle. The patient appears to be physically fit and presents as being alert, oriented, and showing no signs of poor perfusion. Although the heart rate is only 42 bpm and would be reported as bradycardic, it would not be cause for alarm based on the patient presentation. On the other hand, a heart rate of 42 bpm in a 56-year-old male patient who must be aroused with verbal stimuli and has pale, cool, and clammy skin is very concerning. As another example, a heart rate of 92 bpm in an elderly patient at rest would be considered normal; however, a heart rate of 92 bpm in a 20-year-old at rest may be a cause for concern, even though it falls within the definition of a normal range and is not tachycardic. In an elderly patient (greater than 75 years of age), the resting heart rate is normally around 90 bpm. It is not typical for a 20-year-old to have a resting heart rate of 92 bpm;

</table>
thus, you would consider that heart rate to be potentially abnormal and look for possible causes.

To take the pulse rate:

1. Position the patient. He should be sitting or lying down.
2. Using the tips of two or three fingers, palpate the artery (feel it gently). Avoid using your thumb, because it has a prominent pulse of its own.
3. Count the number of beats in a 30-second period. Then multiply by 2. An irregular pulse should be taken for a full minute.

The pulse can help you gauge the patient’s condition. For example, a rapid pulse may indicate shock (hypoperfusion). Absence of a pulse indicates that the heart has stopped beating, the blood pressure is extremely low, or the artery has been blocked or injured. Absence of a pulse in a single extremity may indicate obstruction to the artery in that extremity and may be associated with bone or joint injuries. If so, the patient may complain of numbness, weakness, and tingling, and the skin may gradually turn mottled, blue, and cold.

**Pulse Quality and Rhythm**

The quality of the pulse can be characterized as strong or weak, the rhythm regular or irregular (Table 11-4):

- **Strong pulse** usually refers to a pulse that is both full and normally strong. A “bounding” pulse is one that is abnormally strong.
- **Weak pulse** is one that doesn’t feel full or may be difficult to find and palpate. A weak pulse may also be quite rapid. The general term for a weak, rapid pulse is “thready.”
- **Regular pulse** is usually a normal pulse that occurs at regular intervals with a smooth rhythm.
- **Irregular pulse** is one that occurs at irregular intervals, which may indicate a cardiac disease. An irregular pulse can be regularly irregular or irregularly irregular. A regularly irregular pulse is one in which the irregular beat occurs at a regular interval and has a pattern. An example would be an abnormal beat that occurs early after each fourth regular beat. An irregularly irregular pulse has no predictable pattern and presents as a chaotic rhythm.

Remember to record the pulse quality.

**PATHOPHYSIOLOGY PEARLS**

A weak pulse typically indicates that not enough blood is being ejected from the left ventricle, as associated with volume loss, or that the blood is not being ejected from the left ventricle with enough force, as seen in heart failure. ■

When assessing a pulse, you may note that it decreases in strength or can’t be felt for a short period of time and then returns. If this occurs, look at the patient’s respiratory pattern when taking the pulse. If the pulse weakens or disappears during inhalation, be sure to note it and provide the information in your oral report to the advanced life support unit or medical facility. This could be a sign of pulsus paradoxus. **Pulsus paradoxus** is a decrease in the strength of the pulse during the inspiratory phase of the patient. This may be an indication of a severe cardiac or respiratory injury or illness, or significant blood loss. Another method for determining pulsus paradoxus is upon blood pressure measurement. This will be discussed in the blood pressure section.

**Skin**

The appearance and condition of the skin (Table 11-5) is another important indicator of the body’s perfusion status. In assessing the skin, you should check color, temperature, condition, and capillary refill.

**Skin Color**

Skin color indicates how well the blood is being oxygenated and circulated to the skin and, therefore, how well the lungs and heart (respiratory and circulatory system) are functioning. In all patients, check the color of the nail beds, oral mucosa (mucous membranes of the mouth), and conjunctiva (mucous membranes that line the eyelid). They all should be pink. In infants and children and dark-skinned people, check the palms of the hands and the soles of the feet. They should be pink, too.

Abnormal skin colors include the following:

- **Paleness, or pallor**, may be a sign of extreme vasconstriction, blood loss, or both. It may indicate shock (hypoperfusion), heart attack, fright, anemia, fainting, or emotional distress. Pale, cool, and clammy skin may be an early skin sign of inadequate oxygenation, hypoxia, and hypoxemia.
- **Blue-gray color, or cyanosis**, indicates inadequate oxygenation or poor perfusion. It often appears first in
the fingertips and around the mouth, which is referred
to as circumoral cyanosis. It can indicate conditions
such as suffocation, inadequate respirations, hypoxia,
hypoxemia, heart attack, or poisoning. Cyanosis always
indicates a serious problem but often is seen very late.

- **Red color**, or **flushing**, may be a sign of heat expo-
  sure, peripheral vasodilation, or very late finding in
carbon monoxide poisoning.

- **Yellow color**, or **jaundice**, may indicate liver disease.

- **Mottling** is a discoloration similar to cyanosis; how-
  ever, it occurs as a blotchy pattern. Mottled skin may
  be seen in some shock patients or patients with blood
  pooling in the extremities for a long period of time.

### Skin Temperature

The most common measurement of temperature in the
field is relative skin temperature (Figure 11-5). This can
be assessed by placing the back of your hand against
the patient’s skin. To make your assessment of skin
temperature more accurate, especially in temperature extremes, lift the patient’s shirt and place the back of
your bare hand on the abdominal skin. Relative skin
temperature is not a precise measurement but is a good
indicator of abnormally low or high temperatures. If the
patient has poor perfusion, testing relative skin temper-
ate may provide inaccurate results.

Normal skin feels warm to the touch. Abnormal skin
temperatures include the following:

- **Hot**, which indicates a fever or exposure to heat
- **Cool**, which may be a sign of inadequate circulation,
  shock, or exposure to cold
- **Cold**, which indicates extreme exposure to cold

Changes in skin temperature over a period of time,
or different temperatures in various parts of the body,
can be significant. For example, circulatory problems
result in a cold foot, while an isolated “hot” area
may indicate a localized infection.

### Skin Condition

Normally, skin is dry. Wet or moist skin (often referred
to as clammy skin) may indicate shock (hypoperfusion);
poisoning; a heat-related, cardiac, or diabetic emergency;
or many other conditions. Skin that is both cool and moist
is often described as **clammy**. **Diaphoresis** is the term
used to describe profuse sweating. Skin that is abnormally
dry may be a sign of spinal injury or severe dehydration.

### PATHOPHYSIOLOGY PEARLS

Direct sympathetic nervous stimulation and circulating epi-
nephrine and norepinephrine will cause the vessels in the skin
to constrict, shunting the warm, red blood away from the skin,
which causes the skin to become cool and pale. The nerves
and alpha properties will trigger the sweat glands, making the
skin clammy (moist) or making the patient diaphoretic.
Capillary Refill

The time it takes for compressed capillaries to fill up again with blood is called capillary refill time. It is a more reliable sign in infants and younger children than in older children or adults, since younger children usually have very little existing disease that might affect the perfusion in the capillaries. It is acceptable to assess the capillary refill in the older child or adult patient; however, be aware of the influence a cold environment, preexisting conditions of poor circulation, and certain medications could have on the capillary refill. Keep in mind that capillary refill is only one measure, only a part of the overall picture.

To measure capillary refill, press firmly on the skin or nail bed (Figure 11-6a ■). When you remove your finger, the compressed area will be white (Figure 11-6b ■). Count the time it takes to return to the original color. Normally capillary refill times vary based on the patient’s age, current disease states, and temperature of the environment. When assessed at room temperature, the upper limits of normal capillary refill times are 2 seconds for infants, children, and male adults; 3 seconds for females; and 4 seconds in the elderly. When it takes longer, the circulation of blood through the capillaries may be inadequate, indicating that the patient is suffering from shock (hypoperfusion).

Capillary refill alone does not provide enough information to determine shock. You need to look at the entire patient and other signs and symptoms. Also look at the color of the mucous membranes inside the mouth, conjunctiva, or inside the eyelids, especially in an adult, as a reliable indicator of perfusion status.

Pupils

To assess the pupils, briefly shine a penlight into the patient’s eyes (Table 11-6 and Figure 11-7 ■ ).

- **Size.** Pupils that are *dilated* (large) may indicate cardiac arrest or the use of certain drugs, including LSD, amphetamines, atropine, and cocaine. Pupils that are *constricted* (small) may indicate a central nervous system disorder, the use of narcotics, glaucoma medications, or a brightly lit environment.

- **Equality.** Pupils of unequal size may indicate a stroke, head injury, an artificial eye, disease of the eye, use of certain eye drops, or injury to the eye or nerve that controls the pupil. Some people normally have unequal pupils; if it is a normal condition, however, the pupils remain reactive to light and the size difference is not great (<2 mm). This condition is termed anisocoria. It is usually due to a congenital defect or an ophthalmic injury.

- **Reactivity.** Reactivity refers to the pupil changing in size in response to light shined in the eye. The pupils, which are normally midsize, will constrict when light is shined in them. The pupils will dilate when shaded or in a dark environment. Both pupils will have the same response, even when the light is shined in only one eye. This is called a consensual reflex. For example, you shine a light in the right eye and the right and left pupil constrict simultaneously. Pupils that remain midsize may indicate cranial nerve damage.

Blood Pressure

When the left ventricle of the heart contracts, it ejects blood into the aorta and throughout the arteries of the body. The pressure that is exerted on the walls of the arteries by the blood flowing through them is referred to as the blood pressure. The blood pressure normally includes two readings: the systolic blood pressure and the diastolic blood pressure.

The top number is always the systolic blood pressure, which is the amount of pressure exerted on the walls of the arteries during the contraction and ejection of blood from the left ventricle. The systolic blood pressure correlates with the wave of blood that creates the pulse. Therefore, the pulse is an assessment of the systolic blood pressure. If the systolic blood pressure is low, the pulse will be weak or absent. If the systolic blood pressure is high, the pulse will be bounding (feel very strong). The systolic blood pressure is identified by the first distinct sound (Korotkoff sound) heard when measuring the blood pressure by auscultation (listening with a stethoscope while using a sphygmomanometer, or blood pressure cuff).

The bottom number is always the diastolic blood pressure, which is the amount of pressure on the artery walls while the ventricle is at rest and not contracting. The diastolic blood pressure is related to both the amount of blood in the artery and the diameter of the artery. If the artery is constricted (diameter is made smaller), the diastolic blood pressure will increase. During auscultation, the diastolic blood pressure is recorded when the systolic (Korotkoff) sound disappears or changes drastically.

In a patient who has a reported blood pressure of 128/68 mmHg, 128 is the systolic blood pressure and 68 is the diastolic blood pressure. The systolic and diastolic readings are expressed in millimeters of mercury (mmHg), units that correspond to the marks on the sphygmomanometer gauge.

The blood pressure reading taken with a sphygmomanometer is always expressed as an even number. If the reading falls between two even numbers, the reading is rounded up to the nearest even number. For example, if the systolic sound is heard between 110 and 112, you would not express the reading as 111. You would round the systolic reading up to 112. Electronic blood pressure measurement equipment expresses readings in both even and odd numbers. It is acceptable to report the blood pressure using the numbers provided from the device, but be sure to record on your prehospital care report that the blood pressure was taken by an electronic device.

These devices are referred to as noninvasive blood pressure monitors and will be discussed in more detail later in the chapter under “Monitoring Equipment.”

It is important to assess how briskly the pupils respond to light. Sluggish pupils may indicate a poor oxygen state (hypoxia), drug overdose, or inadequate perfusion. Also note whether both pupils constrict in response to the light. If one or both pupils do not constrict to light shined in one eye, it is referred to as a fixed pupil. Cardiac arrest, severe head injury, severe hypoxia, or extremely poor perfusion to the brain may cause the pupils to become fixed and to dilate. This is referred to as fixed and dilated pupils.

To assess the pupils, first note the size of each pupil. Then shine the light in one eye and watch the response of both pupils. Note if the pupil constricts and how brisk the response is. Remove the light and note if the pupil returns to its resting state and how briskly it responds. Repeat the procedure on the opposite eye.

If the patient is out in bright sunlight or in an extremely brightly lit environment, shade the patient’s eyes before testing the pupillary response. If you do not shade the eyes, the pupils will be normally constricted and will display minimal to no response to a light shined in the eye. Pupils that are dilated, constricted, unequal, or nonreactive may indicate a variety of conditions, as noted in Table 11-6.
Blood pressures vary widely for different patients (Table 11-7). A normal systolic blood pressure in an adult is considered to be less than 140 mmHg. A normal diastolic blood pressure is less than 85. You often hear 120/80 expressed as being the “normal blood pressure.” Actually, 120/80 represents an average, rather than a “normal,” blood pressure for an adult patient. Quick guidelines to determine if the systolic blood pressure falls within a normal range are as follows:

- **Adult male.** In the adult male patient at rest who is less than 40 years of age, add the patient’s age to 10. As an example, a 32-year-old male patient would have an estimated normal systolic blood pressure of 132 mmHg (100 + 32 years = 132 mmHg). A systolic blood pressure greater than 140 mmHg would be considered a mild form of hypertension (high blood pressure). The normal range for the diastolic blood pressure is between 60 and 85 mmHg. Any diastolic blood pressure greater than 90 mmHg is referred to as diastolic hypertension.

- **Adult female.** Since an adult female’s blood pressure is typically 8 to 10 mmHg lower than in an adult male, you would take the patient’s age in years plus 90 mmHg to estimate the normal blood pressure of an adult female at rest. As an example, a 28-year-old female would have an estimated systolic blood pressure of 118 mmHg (90 + 28 = 118 mmHg). The adult female’s diastolic blood pressure is normally 60–85 mmHg. Any pressure greater than 90 mmHg is considered to be diastolic hypertension.

- **Child age 1–10 years.** In children between 1 and 10 years of age, the normal expected systolic blood pressure is calculated by taking the child’s age times 2 and then adding it to 80 mmHg. As an example, the normal expected blood pressure for a 6-year-old child is 92 mmHg (80 + (2 × 6 years) = 92 mmHg). The upper limit of a normal systolic blood pressure would be calculated by taking 90 + (2 × years in age). Thus, the 6-year-old would have an expected upper limit systolic blood pressure of 102 mmHg (90 + (2 × 6 years) = 102). The lower limit of a normal systolic blood pressure would be calculated by taking 70 + (2 × years in age).

The lower limit of a normal systolic blood pressure in the 6-year-old would be 82 mmHg (70 + (2 × 6 years) = 82). The lower limit of normal of a systolic blood pressure in an infant from birth to 1 month of age is 60 mmHg, and from 1 month to 1 year is 70 mmHg. This provides you with a quick reference when estimating blood pressures in children.

The diastolic blood pressure is normally two-thirds the systolic blood pressure. As an example, a child with a systolic blood pressure of 90 mmHg would have an expected diastolic blood pressure of 60 mmHg.

- **Child or adolescent greater than age 10 years.** Children greater than 10 years of age would have a minimum systolic blood pressure of 90 mmHg. A blood pressure less than the minimum expected blood pressure would be a possible indication of shock.

It is important to use the blood pressure as only one indicator of shock or hypoperfusion. Assess the entire patient while looking for other indicators of shock or hypoperfusion. Normal blood pressure could vary widely. Be sure to use many different assessments of perfusion, such as skin temperature and color and mental status. Always treat the patient and not the blood pressure.

The difference between the systolic blood pressure and the diastolic blood pressure is called the pulse pressure. As an example, if the patient’s blood pressure is 124/80, the pulse pressure would be 44 mmHg (124 – 80 = 44 mmHg). If the pulse pressure is less than 25 percent of the systolic blood pressure, it would be considered a narrow pulse pressure. If the pulse pressure is greater than 50 percent of the systolic blood pressure, it would be considered a widened pulse pressure. Using the example just given, a narrow pulse pressure would be less than 31 mmHg (124 × .25 = 31 mmHg) and a widened pulse pressure would be greater than 62 mmHg (124 × .50 = 62 mmHg).

Normally, the two blood pressures rise and fall together. However, there are conditions in which the systolic and diastolic readings become closer together than normal (narrow pulse pressure) or become much further apart (widened pulse pressure). These are important
indicators of possible conditions or injuries that a patient may be suffering. For example, a patient with a head injury may suffer a widened pulse pressure where the systolic blood pressure sharply rises but the diastolic does not rise or even falls. Shock, cardiac tamponade (sac around the heat that is filled with blood and compressing the heart), and tension pneumothorax (one lung is injured and collapses, compressing the heart and uninjured lung) cause a narrow pulse pressure where the systolic blood pressure is falling and the diastolic blood pressure is rising.

**PATHOPHYSIOLOGY PEARLS**

A narrow pulse pressure is usually a result of less blood being ejected from the left ventricle because of either volume loss or left ventricular failure, which causes the systolic blood pressure to decrease while peripheral vasoconstriction causes the diastolic blood pressure to remain stable or increase.

As an EMT, you should note and record any abnormalities in the pulse pressure so that the emergency department can determine trends that may be occurring with the blood pressure. This could lead to suspicion and diagnosis of life-threatening conditions.

A low blood pressure indicates that there is not enough pressure in the arteries to keep the organs supplied with an adequate amount of blood. In an adult patient, a systolic blood pressure of less than 90 mmHg is typically considered to be low, although this is somewhat variable. This can cause an inadequate oxygen delivery to the cells and organs, which in turn can lead to cell and organ damage and death. This condition of inadequate delivery of oxygen and nutrients to the cells and tissues is known as shock or hypoperfusion.

The blood pressure can decrease as a result of blood or fluid loss, cardiac pump failure, or blood vessel dilation (the vessel diameter increases in size). Conditions that may cause shock or hypoperfusion include severe bleeding, heart attack, heart failure, or spinal injury. A low blood pressure may be an indication of these conditions. High blood pressure, also known as hypertension, can result from a variety of causes. The abnormally high blood pressure can cause damage to the heart and blood vessels, leading to heart damage and failure, stroke, ruptured blood vessels, and kidney disease.

It is difficult to assess blood pressure in infants and children less than 3 years of age. Therefore, the EMT should measure blood pressures only in patients greater than 3 years of age. In a child less than 3 years of age, you will rely on the skin temperature, color, and condition; the patient’s mental status; and quality and location of pulses to determine the perfusion status.

**Methods of Measuring Blood Pressure**

There are two methods of measuring blood pressure with a sphygmomanometer: by **auscultation**, or listening for the systolic and diastolic sounds through a stethoscope, and by **palpation**, or feeling for the return of the pulse as the cuff is deflated.

To assess blood pressure by auscultation (EMT Skills 11-1):

1. **Choose the proper size sphygmomanometer cuff.** It should completely encircle the patient's bare arm about one inch above the antecubital space (at the front of the elbow) without overlapping. The cuff should cover two-thirds of the upper arm. Its bladder should be centered over the brachial artery, and cover half the arm's circumference. Properly fitted, the cuff should fit snugly, but you should still be able to place one finger easily under its bottom edge. An improperly sized blood pressure cuff will provide an inaccurate reading. A cuff that is too small will provide a reading that is higher than it should be; a cuff that is too large will provide a reading that is lower than it should be.

2. **Position the arm.** If the patient is seated, position the arm so that the brachial artery at the antecubital fossa is at the level of the heart. If the arm is allowed to dangle, the increase in blood flow due to gravity may provide a false high reading. If the arm is too high above the heart, it may provide a false low reading. If the patient is standing, position the arm at the midchest level. Regardless if standing or sitting, do not allow the patient to support his own arm by holding it up. The strain on the arm may change the blood pressure reading.

3. **Palpate the radial pulse.** Inflate the cuff rapidly to 70 mmHg and then increase by 10-mmHg increments until the radial pulse is no longer felt. Note the number on the dial and deflate the cuff.

4. **Place the stethoscope in your ears with the earpieces facing forward.** Locate the brachial artery on the medial (inner) aspect of the antecubital fossa (front of the elbow). Position the head of the stethoscope over the brachial artery. Be careful not to place the stethoscope under the cuff, which will distort the sounds when listening through the stethoscope.

5. **Close the thumb valve and squeeze the bulb to inflate the cuff.** Inflate the cuff to 30 mmHg above the level noted in step 3.

6. **Slowly turn the thumb valve counterclockwise or press the release mechanism to release air.** Deflate the cuff at approximately 2 mmHg per second, watching the pressure gauge as it slowly decreases.

7. **As soon as you hear the first sound** (clear but dull tapping or swooshing sound), **record the pressure.** This is the systolic pressure.

8. **Continue releasing air from the bulb.** At the point where you hear the last sound, record the diastolic pressure. Continue to deflate slowly for at least 10 mmHg. With children and some adults, you may hear sounds all the way to zero. In those cases, record the pressure when the sound changes from a clear tapping to a soft, muffled tapping.
9. After you have recorded the blood pressure, leave the cuff deflated but in place so you can take more blood pressure readings during treatment and transport. Carefully record the blood pressure each time you take it. Changes can be significant.

To measure the blood pressure by palpation (EMT Skills 11-2):

1. Inflate the cuff rapidly with the rubber bulb while palpating the radial pulse until you can no longer feel it. (Make a mental note of that reading.) Without stopping, continue to inflate the cuff to 30 mmHg above the level where the radial pulse could no longer be felt.

2. Slowly deflate the cuff. Make a note of the pressure at which the radial pulse returns. This is the systolic pressure as measured by palpation. In a noisy situation where you cannot hear well enough to measure the blood pressure by auscultation, this will be the only blood pressure measurement you can make. You will not be able to measure the diastolic pressure by palpation. Record the palpated blood pressure as, for example, 120/P.

A palpated systolic blood pressure is approximately 7 mmHg lower than a systolic blood pressure taken by auscultation.

It was previously thought that the location of a palpable pulse would provide an estimation of the systolic blood pressure. For example, if a radial pulse was felt, the systolic blood pressure would have to be higher than if only the carotid pulse was felt. This was based only on a guess. Research has shown that a radial pulse may be present with a systolic blood pressure as low as 60 mmHg in some patients. Therefore, this method of estimating systolic blood pressure is inaccurate. However, the research did find that it is necessary to have a systolic blood pressure of at least 60 mmHg to produce a carotid, femoral, or radial pulse. Once the systolic blood pressure falls below 60 mmHg, a severe condition of hypotension (low blood pressure), no pulses will be palpable.

Blood pressure should be measured in all patients older than 3 years of age. In infants or young children, however, the general appearance, physical assessment, and quality of pulse are more valuable than the blood pressure.

If, when taking the blood pressure, you note a sudden drop of greater than 10 mmHg, continue with the process. Take another blood pressure and watch for the drop. If the drop is greater than 10 mmHg and is noted during the patient’s inspiration, this is another sign of pulsus paradoxus (as described earlier in the chapter). Note this in your written report and in your oral report to the advanced life support crew or receiving medical facility. Pulsus paradoxus could indicate a serious cardiac or lung illness or injury, or severe bleeding.

In the patient experiencing chest pain, it is important to assess the blood pressure in both upper extremities. If a difference of greater than 20 mmHg is noted between the systolic readings in the two upper extremities, report this finding to the advanced life support crew or the receiving medical facility. This finding may indicate an evolving problem with the aorta in the patient’s chest.

### Testing Orthostatic Vital Signs

In a patient with suspected volume loss, you may be asked to obtain a set of orthostatic vital signs. This is done by placing the patient in a supine position and measuring his blood pressure and heart rate, then standing the patient up and, after 2 minutes, reassessing the blood pressure and heart rate. If, while the patient is standing, the heart rate increases by greater than 10–20 bpm and the systolic blood pressure decreases by 10–20 mmHg as compared to the readings taken while the patient was supine, it is considered to be a positive orthostatic test, which typically indicates a significant loss of blood or fluid volume (EMT Skills 11-3). The orthostatic vital signs test is also commonly known as the tilt test.

---

**Assessment Tips**

When you take orthostatic vital signs, moving the patient from a supine to a standing position provides the best results. A supine-to-seated position will provide orthostatic vital signs if they are present but is not as accurate.

You must be careful when using the systolic blood pressure reading as conclusive in this test, because a large percentage of patients, especially the elderly, experience a normal drop in systolic blood pressure when rising from a supine position even if they have not lost any blood volume. One study indicated that 25 percent of patients over 65 years of age will falsely test positive when an orthostatic tilt test uses a drop in the systolic blood pressure of 10–20 mmHg as the clinical indicator. An increase in the heart rate is a much more sensitive indicator of blood loss when checking orthostatic vital signs. However, bear in mind that some medications, such as beta blockers, may prevent the heart rate from increasing significantly.

If the patient can’t be placed in a standing position, you can move him from a supine to a seated position. Wait the 2 minutes, then reassess heart rate and blood pressure. You will look for the same findings as in the standing patient. However, performing the orthostatic tilt test with a patient in the seated position will not provide the same sensitivity as with the patient in a standing position.

Do not perform this test on patients who you suspect may have a possible spinal injury. It would be imprudent to place this patient in a standing or seated position. When moving a patient from a supine to a standing position, be sure that you assist him and have a good grasp on his body. If the patient has a significant volume loss, he may pass out when moving to a standing position. This would, of course, be a significant indication of volume loss.
**Vital Sign Reassessment**

If the patient is stable, vital signs should be taken and recorded at least every 15 minutes and as often as necessary to ensure proper care. Take and record vital signs every 5 minutes if the patient is unstable. Reassess vital signs immediately following every medical intervention, regardless of how soon it follows your previous assessment of vital signs.

**MONITORING EQUIPMENT**

Specialized equipment may be used to monitor certain aspects of the patient’s status. Two common monitoring devices used by EMTs in the prehospital environment are the pulse oximeter and the noninvasive blood pressure monitor. Many EMTs also use glucometers, or glucose meters, to determine the amount of glucose (sugar) in the patient’s blood. Unlike the pulse oximeter and noninvasive blood pressure monitor, the glucometer does not provide continuous monitoring. It will be covered in detail in Chapter 20, “Acute Diabetic Emergencies.”

**Pulse Oximeter: Oxygen Saturation Assessment**

**Pulse oximetry** is a method of detecting hypoxia in patients by measuring oxygen saturation levels in the blood. The device used to measure the level of hemoglobin saturated with oxygen is a **pulse oximeter** (EMT Skills 11–4). The pulse oximeter probe is clipped, somewhat like a clothespin, or attached by adhesive-backed sensors, onto a patient’s finger, toe, earlobe, or across the bridge of the nose. (Since the pulse oximeter measures arterial blood oxygen saturation, the probe must be placed in an area where the light from the oximeter shines through arterial blood flow. The most common placement in the adult patient is the finger.) One side of the pulse oximeter probe sends out a red light and infrared light. The light shines through the tissue to a photosensor on the opposite side. The light detects the amount of hemoglobin in the blood that is saturated with oxygen and the amount of hemoglobin that is not saturated with oxygen. The pulse oximeter will also measure other gases containing oxygen that may be attached to hemoglobin in the blood, such as carbon monoxide. This will provide an erroneously high SpO₂ reading.

The pulse oximeter provides a reading as a percent of hemoglobin saturated with oxygen. This is recorded as % SpO₂, which indicates the reading was measured by a pulse oximeter. A normal pulse oximeter reading for a person breathing room air is in the high 90s, typically 97–100% SpO₂. A pulse oximeter reading in a compromised patient that is less than 94% may indicate hypoxia. Therefore, any SpO₂ reading of less than 94% in a patient must be investigated and oxygen must be applied to the patient. An SpO₂ reading of 90% or less is an indication of severe hypoxia. Assess your patient carefully, paying close attention to his respiratory rate and tidal volume. He may need to be ventilated if either the rate or tidal volume is found to be inadequate. Whether the patient requires assisted ventilation or not, apply oxygen to the patient. Be aggressive in your management of the patient, bearing in mind that the result of severe and prolonged hypoxia is cell death.

The pulse oximeter is just one tool used in assessment of the patient. It is not the only tool to detect hypoxia. The pulse oximeter reading must be used in conjunction with other assessment findings to make a determination of whether the patient is hypoxic. Treat the patient and not the pulse oximeter reading. However, keep in mind that the pulse oximeter is a sensitive device that may detect hypoxia long before overt signs and symptoms are present.

In addition to indicating hypoxia, the pulse oximeter is a good tool for monitoring the effectiveness of airway management and oxygen therapy and to detect if the patient is deteriorating or improving. If possible, apply the pulse oximeter prior to administration of oxygen so you can measure trends. However, do not delay administration of oxygen to apply the pulse oximeter in a suspected hypoxic patient.

As an example of the pulse oximeter’s effectiveness as a monitoring tool, consider a patient with obvious respiratory distress in whom you apply the pulse oximeter as your partner prepares to administer oxygen by a nasal cannula. You obtain an SpO₂ reading of 92%, indicating hypoxia. Following application of the nasal cannula at 4 lpm, the pulse oximeter reading begins to increase. After 10 minutes on the oxygen, the patient’s SpO₂ reaches 99%. The pulse oximeter readings have shown a dramatic improvement in the patient’s status. On the other hand, if the patient’s SpO₂ reading is 93% on a nonrebreather mask and continues to fall, it is an indication that the patient is deteriorating and may need positive pressure ventilation to maintain or increase the level of oxygenation.

One consideration: If the patient is receiving supplemental oxygen for a period of time and the pulse oximeter reading is near or slightly less than 94%, it may still be an indication that the patient is hypoxic. If the supplemental oxygen were removed, it is likely that the SpO₂ reading would decrease rapidly.

**PATHOPHYSIOLOGY PEARLS**

A patient with a small amount of hemoglobin from blood loss but a large amount of oxygen attached to the remaining hemoglobin may have a high SpO₂ reading, even though his cells are truly hypoxic. When carbon monoxide attaches to hemoglobin, it will cause abnormal absorption allowing the hemoglobin to become red. The pulse oximeter will falsely read this color and interpret it as a high level of oxygen attached to hemoglobin, although the cells are severely hypoxic.
**Indications for Pulse Oximetry**

The pulse oximeter should be applied in any situation in which the patient’s oxygen status is a concern or when hypoxia may be even remotely suspected. In many systems, the pulse oximeter is applied and used routinely on all emergency call patients. The pulse oximeter reading is referred to as a vital sign, indicating that it should be a standard measure in patients along with respirations, pulse, skin, pupils, and blood pressure.

**Limitations of the Pulse Oximeter**

The pulse oximeter needs pulsatile arterial blood flow to determine an accurate reading. Any condition that interferes with the blood flowing to the area where the probe is attached may produce an erroneous reading. The pulse oximeter must be used appropriately, because erroneous readings provide false information and may adversely affect your treatment. As an example, it would be inappropriate to gauge the oxygenation of a cardiac arrest patient by using a pulse oximeter. The perfusion status is too poor for the pulse oximeter to provide accurate or reliable information. Another limitation is that the pulse oximeter does not provide a direct measurement of the blood oxygen content. There is a lag time from when the patient initially becomes hypoxic to when the pulse oximeter reading indicates it, because it relies on an indirect measure of the oxygen content in the blood. Also, it does not indicate the amount of oxygen being off-loaded to cells, the oxygenation status of the cells, or the ability of the cells to use the oxygen. The following are conditions in which the pulse oximeter would produce no reading or an inaccurate reading:

- Shock or hypoperfusion states associated with blood loss or poor perfusion will lead to inaccurate readings.
- Hypothermia or cold injury to the extremities will reduce peripheral perfusion and limit the blood available in the capillaries to be read by the probe.
- Excessive movement of the patient (for example, during some types of seizures) will lead to inaccurate readings.
- Nail polish on the finger the probe is attached to will produce an inaccurate reading. Clean the fingernail with an acetone wipe before applying the finger probe.
- Carbon monoxide will give an abnormally high reading although the cells are actually becoming severely hypoxic. Carbon monoxide binds with the hemoglobin in the blood and absorbs light at the emitted frequencies, creating a red tone. The pulse oximeter erroneously reads the absorbed light of hemoglobin attached to carbon monoxide molecules, providing a false high reading.
- Cigarette smokers may have falsely high SpO₂ readings, because carbon monoxide is a by-product of the smoke. Up to 15 percent of the hemoglobin may be bonded with carbon monoxide, not oxygen, giving a false high reading.
- Anemia may produce abnormally high readings. The hemoglobin may be saturated with oxygen, but the anemic patient has decreased levels of hemoglobin. The hemoglobin is saturated with oxygen, but the combined hemoglobin-oxygen content of the blood is inadequate.

Most pulse oximeters display a pulse rate along with the SpO₂ reading. If the pulse rate shown on the pulse oximeter does not correspond with the patient’s actual pulse rate, there is a good chance that the pulse oximeter is also not accurately reading the blood flow and oxygen saturation.

To elaborate on the point just listed about carbon monoxide: In a carbon monoxide poisoning patient, the pulse oximeter reading will be excessively high, but totally inaccurate. This patient may be severely hypoxic and still have an SpO₂ reading of 100%. This occurs because the pulse oximeter measures the percentage of hemoglobin that is saturated. The pulse oximeter cannot distinguish between hemoglobin saturated with oxygen and hemoglobin saturated with carbon monoxide. With carbon monoxide having an affinity for hemoglobin that is 200–300 times greater than oxygen, a large amount of carbon monoxide having an affinity for hemoglobin that is inadequate.

Again, remember to assess the patient as a whole. The SpO₂ reading is just one tool in that assessment.

**Procedure for Determining the SpO₂ Reading**

To determine the patient’s SpO₂ level:

1. Connect the sensor to the SpO₂ monitor device.
2. Attach the probe to the fingertip. In an infant, the toe or distal foot can be used.
3. Turn on the device and wait for a few seconds for the reading to appear. Match the pulse reading on the SpO₂ monitor with the patient’s. If the heart rate is different, it is likely the SpO₂ reading is inaccurate.
4. If a poor signal is detected or an “error” reading is indicated, check the probe to be sure it is on properly. Check for nail polish on the fingernails. Remove the nail polish or change the probe to another fingertip.
5. Once an accurate reading is provided, reassess and document the SpO₂ reading every 5 minutes in the unstable patient, every 15 minutes in the stable patient.
When arriving on the scene, you will frequently encounter patients and family members who are frightened, injured, anxious, or in shock. In addition, you may find an angry or hostile crowd and law enforcement or fire department personnel anxiously awaiting your arrival. You must display competence, confidence, and compassion—through your personal appearance and professional manner—in order to obtain cooperation not only from the patient but also from others at the scene. Prior to obtaining a history or performing a physical examination it is necessary to gain control of the scene. The entire history or parts of the history might be sought and obtained from Emergency Medical Responders, relatives, or other caregivers at the scene. By using the following techniques, you should be more successful in taking the history and obtaining the necessary information.
Achieve a Smooth Transition of Care

When you arrive on the scene, it is important to achieve a smooth transition of care from an Emergency Medical Responder, police officer, or other individual who is providing first aid. Announce your arrival by stating, for example, “I’m John Brady and this is Susan Kechlow. We are emergency medical technicians. Can you tell us what has happened and what care has been given?”

If the patient appears to be alert and responsive, you will have time to quickly gain information from the Emergency Medical Responders before you make actual patient contact. This should take less than 1 minute. Do not carry on a conversation that is irrelevant to the patient, as this tends to ruin your presentation of confidence, competence, and compassion. An unresponsive or obviously injured patient needs your immediate attention. In this situation, proceed directly to the patient and obtain information from others at the scene as you begin to perform your primary assessment.

Reduce the Patient’s Anxiety

Once you make contact with the patient, attempt to reduce his anxiety and that of others at the scene. You can do this by employing the following simple techniques:

1. Bring order to the environment.
2. Introduce yourself.
4. Position yourself.
5. Use communication skills.
6. Be courteous.
7. Use touch when appropriate.

Bring Order to the Environment

As quickly as possible, bring order to the environment by asking that televisions or radios be turned down, dogs removed from the area in which you are working, and children supervised by a family member, police officer, or Emergency Medical Responder. Do not walk up to a television and simply turn it off while someone is watching it. No matter how serious the situation or patient appears, there are people who become extremely agitated when treated in this manner. You would be setting yourself up for a possible violent confrontation. You must explain, for example, “It is extremely important that you turn the television off so that we can hear and focus on caring for your mother.” If the person refuses, ask for the sound to be turned down or remove the patient as quickly as possible from the scene.

Remember, not everyone at the scene is happy to see you. Some people will become agitated and resist your simple requests. You must remain calm and non-confrontational and continue to focus on patient care.

Introduce Yourself

Introduce yourself and ask for the patient’s name. Address older individuals formally as “Mr. Jones” or “Mrs. Smith” to avoid any implication of disrespect. If time or the situation permits, you can ask, “What would you like me to call you?”

Gain Patient Consent

Gain consent from the patient. This step is necessary before you may legally provide emergency care. You can do it simply by asking, “Is it all right for me to help you?” If the patient has an altered mental status, is unresponsive, or is unable to make a rational decision, provide emergency care based on implied consent.

If the patient refuses your assistance, do not immediately pack up your equipment and pull out the refusal form, ready for the patient’s signature. Many times the patient initially refuses care out of denial (a normal, and usually temporary, psychological response in which the patient cannot accept that he is ill or injured) or because he is frightened or confused. Keep talking with the patient to establish a rapport and help the patient accept the need for you to assess and treat him. If necessary, enlist the aid of a family member in convincing the patient. If the patient continues to refuse, contact medical direction for advice on how to proceed. Refer to Chapter 3, “Medical, Legal, and Ethical Issues,” for further discussions on the legal implications of patient consent and refusal of emergency care.

Position Yourself

Your body position and posture are forms of nonverbal communication. Position yourself at a comfortable level in relation to the patient. If the eye levels are equal, so is the authority. If you are standing over the patient, you are in a dominant position of authority and control. This may be uncomfortable for the patient and may set the wrong tone for the scene. (At some scenes, when you need to establish control, this position is warranted.)

In the general American culture, intimate space generally starts at about 18 inches from the body. Unless you are intentionally touching your patient (see the next section), the patient is likely to be most comfortable if you maintain at least this distance from him during history taking or other conversation.
Standing with your arms crossed over your chest is a closed communication posture, conveying hostility or disinterest. Instead, you want to display an openness and willingness to help.

**Use Communication Skills**

As much as possible, maintain eye contact when talking with the patient to help establish rapport and to convey your sincere concern.

Speak calmly and deliberately to allow the patient to process the information. Raise your voice only if the patient appears to be hearing impaired. An elderly patient is not necessarily hard of hearing. Speak slowly, clearly, and directly to elderly patients. Give them additional time to respond to each question. Also speak in a calm and confident manner when you are communicating to your partner or others at the scene. Yelling or screaming while directing the scene and giving orders will only increase the anxiety of the patient and bystanders and exhibits a loss of control on your part.

Your body movements should be purposeful, displaying competence and confidence, and not hasty or jerky.

Actively listen to what the patient is telling you. This avoids having to unnecessarily, and annoyingly, ask the same question several times. Make sure that the patient realizes you are listening by leaning forward, maintaining eye contact, and not allowing your attention to wander while the patient is talking to you.

**Be Courteous**

The scene of an emergency is very stressful. As a result, the patient, family members, and bystanders may not be at their best. They may often seem quarrelsome, petty, rude, or hostile. As a professional, you must resist yielding to the same stresses. Try to understand why people behave as they do, and maintain a courteous manner throughout the call.

**Use Touch When Appropriate**

Touching the patient is a powerful comfort measure when dealing with most people. Use eye contact to avoid the patient’s perception of the touching as encroachment. Hold a hand, pat a shoulder, or lay your hand on a forearm. In order for touch to be effective, you must be sincere in your gestures, not using them as a gimmick.

**Maintain Control**

It is difficult to conduct an assessment, gather information from the patient, and provide emergency care at a scene that is not controlled. The greater the distractions at the scene, the higher the anxiety level of the patient, family, and bystanders. Use the scene control measures described earlier to lessen confusion, reduce anxiety, and convey a professional attitude that the patient is in the care of capable EMTs.

It is important to recognize when a scene cannot be adequately controlled. It may be impossible to gain scene control when the crowd is extremely hostile, the family is emotionally charged or upset, threats are being made toward you, or the scene is unstable because of the risk of fire, explosion, or other hazards. You must consider your own safety when working in an uncontrolled environment. If the scene remains uncontrolled, it is best to move as rapidly as possible to remove yourself and the patient from the scene and/or to call for additional resources as needed.

**TAKING THE HISTORY**

Information gained in the history is as important in most medical cases as the information determined through the physical examination. The history typically begins with determining the **chief complaint**. The chief complaint is the reason why the EMS crew was called to the scene. You will continue with obtaining information about the present illness, significant past medical history, and the current health status of the patient. The information gathered may provide direction for the physical examination. Often, the history and physical examination are conducted concurrently depending on the resources at the scene and the condition of the patient. Although a structured approach to history taking will be presented, the process must remain dynamic to allow you to pursue pieces of information provided by the patient or other persons as they are presented.

The best source to gather the history from is the patient. If that is not possible, you can attempt to obtain history information from the family, friends, bystanders, other emergency responders, medication containers, medical identification tags, and any other source possible. When using sources other than the patient, the accuracy of the information may be questionable.

Once the chief complaint is obtained, you will proceed with a history of the present illness. This is a more detailed evaluation of the chief complaint and associated signs and symptoms. Other components include demographic information, current health status, and past medical history. You may need to ask questions about sensitive topics such as alcohol or drug use or sexual history. You will build your history-taking technique and become comfortable through practice and experience.
Statistical and Demographic Information

Certain data will be collected for statistical, record-keeping, and demographic purposes. These data include the following:

- **Date.** Be sure to document the correct current date and dates of information provided by the patient regarding complaints, signs, treatments, illnesses, hospitalizations, and any other pertinent information.
- **Time.** Document the time of events accurately.
- **Identifying data.** Record the patient’s age, sex, and race.

Current Health Status

Determine the current health status of the patient relevant to the chief complaint and medical illness or injury. The current health status focuses on the patient’s present state of health. Take into consideration environmental and individual factors. Environmental conditions may include what the patient is exposed to at work, in the home, or in recreational activities. Individual factors to consider are:

- Current medications, including prescription and over-the-counter medications
- Allergies to medications or other substances, including specific reactions experienced in the past
- Tobacco use, including type of tobacco and how much
- Alcohol, drugs, and related substances
- Diet, including daily food and drink intake
- Screening tests that may have been done recently
- Immunization against certain diseases
- Environmental hazards the patient is exposed to
- Use of safety equipment such as seat belts and bike helmets
- Family history, especially for disease with a hereditary link

Techniques for Taking a Patient History

Certain techniques that can be used to better facilitate the history-taking and information-gathering process are described next.

Note Taking

Document the information the patient provides as accurately as possible. It is typically impossible to remember all the information the patient provides, especially when you are doing multiple calls back-to-back. The information seems to meld together and it is sometimes difficult to recall the history of the current patient and not confuse it with information gained from previous patients in the day. Thus, it is not only acceptable but also necessary to take notes to present the most accurate information as possible.

Types of Questions

There are basically two types of questions used by EMTs to gather a history: open-ended questions and closed-ended questions. An open-ended question requires the patient to respond with a descriptive or more detailed answer. “How are you feeling today?” and “Can you describe the discomfort?” are examples of open-ended questions. The patient is unable to provide a “yes” or “no” answer to open-ended questions.

A closed-ended question is often a rapid-fire-type question that requires only a “yes” or “no” answer. “Are you having pain in your chest?” and “Do you feel light-headed?” are examples of closed-ended questions. Often, both types of questions are used throughout the history. A multiple-choice question that uses a mix of both formats may also be used. “When are you more short of breath: when you lie flat or when you sit up?” is an example of a multiple-choice question.

The patient’s condition may require that you use more of one type of question than the other. If a patient is struggling to breathe because of an acute asthma attack, you don’t want him expending lots of energy trying to provide long answers to your open-ended questions. Thus, you would use rapid-fire, closed-ended questions to gather a great amount of information in a short time with less effort on the patient’s part. Be careful, however, since it is easy to lead the patient with closed-ended questions. You might find a patient answering “yes” to all the questions, even the ones that contradict each other.

To determine the chief complaint, use an open-ended question. “Why did you call EMS?” or “What seems to be the problem today?” are often used to elicit a chief complaint. Be aware that the chief complaint is not always the primary problem. For example, the patient states “My belly hurts” when asked why he called EMS. However, as you pursue the history you find that he has had the belly pain for 3 weeks and called EMS today because he had bloody diarrhea.

Be sure to use plain English and not medical terminology when asking any of the questions.

Active Listening Techniques

Listen actively to your patient and provide responses or gestures that indicate you understand. The following are active listening techniques.

- **Facilitation.** Maintain eye contact with the patient in a sincere manner. Use posture, actions, words, facial
expressions, or cues while listening to help your patient feel comfortable, open up, and provide more information. Phrases such as “I’m listening” or “Go on” may be used.

- **Reflection.** Repeating the patient’s words will encourage him to provide additional responses. Avoid interrupting the patient’s train of thought while practicing reflection. This may encourage the patient to reveal information you might not otherwise have discovered. The patient states, “My belly hurts,” as a response to your open-ended question to gather the chief complaint. “Your belly hurts?” is your response. The patient then states, “Yes, it has hurt ever since I haven’t had a bowel movement for this past week.” Your response is, “You haven’t had a bowel movement for a week?” The patient then responds with, “No, it has been more than a week and my belly began hurting a few days ago.” As you can see, the chief complaint has changed its focus from abdominal pain to a possible bowel obstruction.

- **Clarification.** Clarification is used to clarify ambiguous statements, responses, symptoms, or words. The patient states, “I feel bad all over.” You then clarify by asking, “Can you describe what the bad feeling feels like?” The patient responds with, “It feels like pins and needles in my arms and legs.” The clarification technique provided a much more descriptive symptom.

- **Empathetic Response.** Show empathy through verbal responses and gestures. “I understand” or “I see how that would be difficult” are some verbal responses that show empathy.

- **Confrontation.** Sometimes patients will not provide the entire truth or will try to downplay symptoms. You may need to confront them to determine the accurate information. “You said you have never been to the doctor, yet there is a prescription for Glucophage in your name on the table” is an example of confrontation.

- **Interpretation.** Interpretation takes confrontation to the next level. You may need to make an inference based on your observations. As an example, “You say you have never been to the doctor, yet you have a prescription medication in your name. Are you afraid your current medical condition is worsening and you might have to be admitted to the hospital?”

**Standardized Approach to History Taking**

**The Sample History**

The **SAMPLE** history is a medical history of the patient that you gather by asking questions of the patient, family, and bystanders. **SAMPLE** is a mnemonic (memory aid) used to help you remember the information that must be included in a patient history. It spells out the first letters of the following categories:

- **Signs and symptoms.** Signs are any objective physical evidence of medical or trauma conditions that you can see, hear, feel, or smell. For example, you can hear stridor, you can see bleeding, and you can feel skin temperature. Symptoms are conditions that cannot be observed and must be described by the patient, such as pain in the abdomen or numbness in the legs. When you begin to question the patient, ask: “What are you feeling? When and where did the first symptoms occur? What were you doing at the time?” Another mnemonic used to evaluate the patient’s symptoms is **OPQRST** (onset, provocation/palliation, quality, radiation, severity, and time).

- **Allergies.** Determine whether the patient has any allergies to medications, food, or environmental agents such as pollen, grass, ragweed, or molds. Ask about the type of reaction to the allergen, such as a rash or wheezing. If you have not already done so during the physical exam, check for a medical alert tag, necklace, anklet, or bracelet, which can alert you to an allergy or other medical problem.

- **Medications.** Has the patient taken any medications recently? Is the patient taking any medications regularly? It is important to determine if the patient takes (1) prescription medications, (2) nonprescription or over-the-counter medications, (3) birth control pills, (4) illicit drugs, (5) herbal medications, (6) erectile dysfunction drugs, (7) another person’s prescription medication, or (8) vitamins. If you suspect illegal drug use, you might say something like, “I’m an EMT, not a police officer. I need all the information you can give me so I can provide the proper care. Let’s work on helping you right now.” As with allergies, look for a medical alert tag if the patient is unresponsive.

- **Pertinent past history.** Find out about underlying medical problems like seizures, heart disease, diabetes, kidney disease, or emphysema. Ask if there have been past surgical procedures or trauma, and whether the patient is currently under a doctor’s care. Again, look for a medical alert tag if the patient is unresponsive.

- **Last oral intake.** Find out when the patient last ingested a solid or liquid. Find out what it was, when it was consumed, and the quantity that was consumed. Ask: “When did you last eat or drink anything?”

- **Events leading to the injury or illness.** What occurred before the patient became ill or had the accident? Were there any unusual circumstances? What was the patient doing? Did the patient have any peculiar feelings or experiences?
ASSESSMENT TIPS

When patients are asked about their last meal, they often interpret this as breakfast, lunch, or dinner, which may have been several hours from the time of the call, and not provide information about snacks between meals, which may have occurred very close to the time of the call. That is why you ask about last oral intake and not the last meal.

As you conduct a SAMPLE history, try to get more detailed information about the conditions that are directly related to or that could adversely affect the present problem. If you are caring for a burn victim, for example, it would be important to learn if there are underlying cardiac or respiratory problems that might impair breathing. It would not be relevant to learn that the patient had a hernia surgery 5 years ago or had measles as a child.

Assessing Patient Complaints: OPQRST

OPQRST is a mnemonic for remembering the questions to ask when assessing the patient’s chief complaint or major symptoms, such as pain, that the patient can tell you about. Your questions should determine the onset, provocation/palliation, quality, radiation, severity, and time of the complaint.

- **Onset.** When and how did the symptom begin? Ask the patient if the onset was sudden or gradual. Also determine if the onset was associated with a particular activity. For example, you arrive on the scene and find a patient complaining of chest pain. The patient states the onset of the chest pain was sudden. You then ask, “What were you doing when the chest pain started?” The patient replies, “I was playing tennis at the time.” Based on this response, you would document the onset of chest pain as being associated with strenuous activity.

- **Radiation.** Where do you feel the pain? Where does the pain go? Prior to asking about radiation, it is necessary to determine the exact location of the pain. Ask the patient to point to the pain with one finger. The pain is localized if he can isolate it to one area. Generalized pain cannot be localized and is spread over a general area. From the point of the initial pain, ask if the pain extends, moves, or radiates. Commonly, pain associated with the heart radiates to the arms, neck, and back. Pain associated with an aortic aneurysm (a weakened and ballooned segment of the wall of the aorta) commonly radiates to the back in the lumbar region or to the groin. Kidney stones commonly produce pain in the flank area (side) that radiates down along the groin.

- **Severity.** How bad is the symptom? How bad is the symptom? Ask the patient to rate the pain on a scale of 1 to 10 with 10 being the most severe. Have the patient compare the pain with a previous condition he may have suffered that involved pain. The patient’s appearance should give you some indication as to the severity of the pain. Is the patient squirming about in pain or easily distracted from the pain?

- **Time.** How long have you had the symptom? Determine if the symptom has been present for minutes,
hours, days, weeks, months, or years. If you get called to the scene and find a patient complaining of a symptom that has been present for more than a day, ask the patient, without appearing to be judgmental, “Why did you call us today?” If the symptoms have been present for a few hours or more, ask the patient, “Was there any change in the symptoms that caused you to call?” Most times the patient will call EMS when the pain gets worse, changes in quality, or if other associated signs or symptoms occur. Do not assume that a patient suffering pain or some other symptom accesses EMS immediately. Document the length of time the symptoms have been present.

To gather the most effective information, ask open-ended questions when you can—ones that cannot be answered merely “yes” or “no” but require a fuller response or description from the patient. Then wait for the patient’s response. Whenever trauma is involved, try to identify the mechanism of injury (the manner by which the injury occurred) through observation or questioning. Pertinent negatives, things the patient denies, are also important to note. For example, if you ask a patient with chest pain if he is short of breath and he says no, you would document “Patient denies having shortness of breath.” Finally, remember to write all pertinent findings from the SAMPLE history on the prehospital care report.

Sensitive Topics or Special Challenges

Sensitive Topics

It may be necessary to ask questions in the history that you might consider to be sensitive in nature, such as alcohol or drug use, physical or sexual abuse, or sexual history. When asking questions that may be sensitive, remain nonjudgmental and only ask questions that pertain directly to the medical history and are necessary to gain answers that are pertinent to your assessment and emergency care. Respect the patient’s privacy and ask questions of a sensitive nature at the appropriate time and in an appropriate location. You are not a mental health professional and are not trained in counseling; thus, your interaction with the patient on sensitive topics must remain within the scope of your practice.

Special Challenges

Some patients create special challenges to gathering a history. Typically, as you become more experienced and build a solid technique for history taking, the challenges become easier to manage. Some of the challenges are:

- **Silence.** Silence can be uncomfortable for both you and the patient. Attempt to determine why the patient has become silent. It may be due to several factors. The patient may have suffered a medical condition such as a stroke or brain injury that renders him unable to speak. The patient may just need time to respond to your question. This is often true in the elderly. The patient may be overwhelmed with the situation or you may have asked too many questions and he is trying to sort his thoughts. Provide the patient adequate time to respond. Watch his body language for nonverbal clues such as crying; facial expressions of anger, confusion, or depression; a closed body posture; and signs of being tense. Try to determine the cause for the silence, rectify it if possible, and proceed with the history.

- **Overly talkative patient.** Some patients will continue to talk and not allow you enough time to ask questions. Give your patient a free rein for a period of time to talk and express himself. You can interrupt him and summarize his statements frequently. You can also proceed to closed-ended questions in an attempt to control the history. Maintain patience and gather as much information as possible.

- **Patient with multiple symptoms.** Some patients will present a multitude of complaints. The challenge is attempting to determine the true chief complaint. You will need to use clarification to bring the patient to a primary chief complaint. Asking “But why did you call today?” or “What was the primary reason for calling us today?” may assist you in determining the actual chief complaint.

- **Anxious patient.** Many patients experience anxiety in an acute emergency. The patient may exhibit many nonverbal clues such as sweating, nervousness, trembling, and tachycardia. Encourage the patient to freely express his feeling of anxiousness or anxiety. The best approach you can take is to provide reassurance.

- **Angry and hostile patient.** Anger and hostility are a natural part of illness and injury. Because you are likely to be the first medical person to provide care for the patient, it may be that the patient or family directs the anger toward you. They are not really angry at you, even though it may appear that way. Remain calm, confident, professional, and competent. Accept the patient and family members’ feelings. Do not become frustrated, angry, or defensive.

- **Intoxicated patient.** The most significant concern with an intoxicated patient is your own safety. An intoxicated patient may suddenly change his behavior and become violent. Always remain vigilant when dealing with an intoxicated patient. The easiest way to deal with this patient is not to challenge but to accept him. Do not ask the patient to lower his voice or stop pacing. Listen to what the patient is saying through the loud voice, shouting, or
cursing. Avoid trapping the intoxicated patient in a small area as well as any other behavior that may appear threatening to the patient. Remain nonjudgmental and attempt to provide assistance to the patient. In some cases it may be necessary to involve law enforcement to protect yourself, the patient, or bystanders.

- **Crying patient.** Crying is a nonverbal clue to the patient’s emotions. Be patient, empathetic, and supportive. It is okay to allow the patient to cry. Provide reassurance and remain supportive.

- **Depressed patient.** Look for signs of depression such as weight loss, flat affect, poor eye contact, insomnia, loss of appetite, fatigue, or complaints of aches or pains. Listen carefully to the patient and remain nonjudgmental. If there are signs of serious depression, such as thoughts of suicide, be sure to get the patient the assistance and care that he needs.

- **Confusing behavior or history.** A patient who presents with a confusing history or bizarre or unusual behavior may be suffering from a mental illness, dementia, or delirium. Dementia is associated with a gradual decline in the mental status of the patient due to some type of neurological disease. Delirium is an acute alteration in the mental function of the patient that is usually due to a reversible cause such as intoxication or drug use. Do not spend an excessive amount of time trying to collect a history in these patients.

- **Patient with limited intelligence.** The patient will often be able to provide you with adequate history information. Be alert to possible omissions of information. If the patient has a severe cognitive impairment, obtain the history from the family or caregivers.

- **Language barrier.** If the patient speaks a language that you are not fluent in, try to find an interpreter such as a family member. Realize that some history information may be confused or lost in the translation. If a translator is not available, contact a telephone translation service or transport the patient and notify the hospital of the need for a translator.

- **Hearing impairment.** Hearing impairment offers many of the same challenges as a language barrier. The advantage in this situation, however, is that you can revert to writing to ask questions and obtain information. When speaking to a hearing-impaired person, face the patient and look at him when you speak. Such patients often read lips. Use a person who can sign as your translator if available.

- **Visual impairment.** Remember to tell the visually impaired patient everything you are doing. These patients cannot see your movements or hand gestures. You may increase their anxiety significantly if they are not continuously made aware of what is happening at the scene. Constantly communicate with the patient.

- **Talking with friends and family.** Some patients will only be able to provide limited information. You may need to rely on family members or friends to fill in the gaps or provide the entire history. Family or friends may be very useful in providing information about the events leading up to the emergency.

- **Pediatric patient.** The pediatric patient may present with special challenges based on ability to understand the questions you are asking. A child may not have the ability to respond appropriately. Once the child reaches 4 years of age, he should become the primary source of the history. Use the parent or caregiver to fill in the gaps.

- **Elderly patient.** The elderly patient may have physical limitations such as impaired sight or hearing that make history gathering a challenge. Do not assume that an elderly patient suffers from dementia. If mental impairment seems evident, ask family or friends if this is the patient’s normal presentation or if it may be a result of the current medical condition or emergency. Normally, the elderly patient should be the primary source for the information. Be patient and, if necessary, allow extra time for responses to your questions.
EMT SKILLS 11-1

Taking Blood Pressure by Auscultation

- **11-1A**  Apply the cuff.
- **11-1B**  Palpate the brachial artery.
- **11-1C**  Close the valve and pump until the radial pulse is no longer felt. Note the number and deflate the cuff. Position the stethoscope over the brachial artery and inflate the cuff to 30 mmHg above the level where you previously stopped feeling the radial pulse.
- **11-1D**  Deflate the cuff at about 2 mmHg per second. When you hear the first sound, record the pressure (systolic). Continue releasing air. When you hear the last sound, record the pressure (diastolic).

EMT SKILLS 11-2

Taking Blood Pressure by Palpation

- **11-2A**  Apply the cuff and inflate rapidly to 30 mmHg above the level where you can no longer feel the radial pulse.
- **11-2B**  Slowly deflate the cuff. Note the pressure at which the radial pulse returns (systolic). You will not be able to measure the diastolic pressure by palpation.
EMT SKILLS 11-3

Taking Orthostatic Vital Signs

11-3A Place the patient supine and measure heart rate and blood pressure.

11-3B Help the patient to a standing position, wait 2 minutes, then measure heart rate and blood pressure. Compare the readings to those taken while the patient was supine. An increase in heart rate more than 10–20 bpm and a decrease in blood pressure by 10–20 mmHg is considered a positive orthostatic test, indicating inadequate blood volume.

EMT SKILLS 11-4

Pulse Oximetry

11-4A A pulse oximeter.

11-4B A pulse oximeter placed on the patient’s finger.

11-4C A mini “finger-size” pulse oximeter.
Chapter Review

SUMMARY

Assessing vital signs is an important EMT function. You will take vital signs on every patient you encounter. These vital signs are typically the first ones taken in the emergency situation and are often used as the baseline from which the medical team gauges changes in the patient’s condition. You will often take several sets of vital signs on each patient in an attempt to identify trends in the patient’s condition, that is, whether he is improving or deteriorating. The vital signs cannot be used as the sole indicator of the patient’s condition but, instead, must be viewed in the context of the whole patient along with other indicators, such as signs and symptoms.

The six vital signs that you will assess are respirations, pulse, skin, pupils, blood pressure, and pulse oximetry. In a stable patient the vital signs are assessed every 15 minutes, whereas they are assessed every 5 minutes in the unstable patient.

Obtaining a history is important in determining the condition of the patient and what emergency care is necessary, especially in the medical patient. You will often use closed-ended questions in the trauma patient where history is less important and in those who are having trouble responding. Open-ended questions are used in the medical patient and generally provide more information. You must be prepared for many challenges in history taking.

Case Study Follow-up

Scene Size-up

You have been dispatched to the scene of an 86-year-old male who lives alone. His daughter, who found him, reports that the patient, Mr. Li, fell early this morning and was unable to get up. As you and your partner enter the home, you note no safety hazards.

Upon entering the kitchen, you see Mr. Li supine on the floor, eyes closed, with a blanket covering him from shoulders to feet. The kitchen is very tidy and clean. The daughter, Ms. Kennedy, says she thinks he fell off a chair he had been standing on to reach the top of a cupboard.

Patient Assessment

You crouch next to Mr. Li as your partner provides manual stabilization of his head and neck and ask, “Are you okay?” He opens his eyes and responds, “I think so.” You check for life-threatening problems with the airway, respiration, and circulation and find none. You conduct a more thorough exam before you transport Mr. Li to the hospital.

You conduct a head-to-toe physical exam (during which you discover that Mr. Li is wearing a bracelet identifying him as a diabetic), and apply a spinal cervical immobilization collar. Then you obtain a set of baseline vital signs. Your findings are: respirations 18 and normal; pulse 78 and regular; skin pink, warm, and dry; pupils normal, equal, and reactive; blood pressure 168/82 mmHg; and SpO₂ is 98%. Because there are no signs of hypoxia, hypoxemia, or poor perfusion; no complaints of dyspnea; no evidence of respiratory distress or heart failure; and the SpO₂ reading is 98% on room air, you elect to not administer oxygen. However, you will continue to closely monitor the patient’s condition and oxygenation status.

Finally, you gather a SAMPLE history. By questioned Mr. Li and his daughter, you learn that Mr. Li’s main symptom is the pain in his left hip, which he says was brought on by the fall several hours ago. In answer to your questions, he says the pain is especially severe when he tries to move his left leg, describes the pain as sharp, and says it does not radiate to any other location. Mr. Li also states that he is allergic to penicillin to which he develops a rash. Questioned about his medications, he says he takes insulin daily to help control blood sugar. When you ask about pertinent past history, the daughter confirms that Mr. Li has a history of diabetes and tells you that he had both hip joints replaced in 1989. You inquire about last oral intake—what Mr. Li last ate or drank—and Mr. Li says he has not eaten a meal since dinner last night. Ms. Kennedy adds that while they were waiting for the ambulance, she gave her father a glass of water. The patient describes the events that led to the injury by explaining that he slipped and fell from the chair at about 11:00 a.m.

You prepare your patient for transport by applying a splint to the left leg and hip, immobilizing him to a long spine board, securing him to your wheeled stretcher, and placing him in the ambulance.

En route to the hospital, you reassess Mr. Li’s airway, respiration, oxygenation, and circulation and find no abnormalities. You frequently check that he is comfortable and that he is properly secured to the splint, spine board, and stretcher. Because Mr. Li’s condition is considered stable, you repeat and record his vital signs every 15 minutes before reaching the hospital without finding any significant changes. Transport is uneventful, and you transfer Mr. Li to the emergency department personnel. After completing a prehospital care report, you and your partner prepare the ambulance for the next call.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.
IN REVIEW

1. Identify the components of vital signs, and state how often they should be taken.
2. Explain how to assess a patient’s respiratory rate and quality of breathing. Also state the normal ranges of respirations per minute for the adult, child, and infant.
3. Describe what you would observe when a patient is breathing normally and when a patient is breathing abnormally.
4. State the general circumstances under which you would choose to take a radial pulse, a brachial pulse, or a carotid pulse.
5. Explain how to take a pulse. Also identify normal resting pulse rates in an adult, adolescent, school-age child, preschool child, and infant. Define the terms that you would use to describe pulse quality.
6. List the places on the body to check for skin color. Also identify normal and abnormal skin colors.
7. Explain how to assess a patient’s pupils, and describe normal and abnormal findings.
8. Explain how to take a blood pressure by palpation and by auscultation. Also identify the normal ranges of systolic and diastolic blood pressure for an adult male and an adult female.
9. Explain the indications for and limitations of pulse oximetry. Explain how to take an SpO2 reading.
10. Name the categories of information you need to obtain through a SAMPLE history.
11. List the information collected by using the OPQRST mnemonic.
12. Describe special challenges to history taking and methods of how you would overcome each challenge.

CRITICAL THINKING

You are called to a residence for a patient who has fallen. A neighbor has made the call to 911. Upon your arrival, you find a 56-year-old male patient who has fallen from the roof of his house onto the concrete driveway. As you approach the patient, he is not alert and has severe trauma to the head. It appears he has fallen head first. He has a large amount of blood coming from his mouth, nose, and ears. You hear gurgling sounds with each respiration. His respirations are rapid at approximately 45 per minute with minimal chest movement. His radial pulse is slow at a rate of 48 per minute, but strong. His BP is 198/72 mmHg. The SpO2 reading is 76% on room air. His skin is cyanotic, warm, and dry. His wife arrives home while you are on the scene and begins to scream frantically.

1. What is the significance of the gurgling sound?
2. How would you document the pulse rate?
3. What does the pulse oximeter reading indicate?
4. What do the skin signs indicate?
5. What other vital signs would be important to assess in this patient?
6. When would you attempt to gather a SAMPLE history?
7. How would you gather the SAMPLE history?
8. What information would you be able to gather using the OPQRST mnemonic?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Assessment** (Content Area: Scene Size-Up)

**COMPETENCY •** Applies scene information and patient assessment findings (scene size-up, primary and secondary assessment, patient history, and reassessment) to guide emergency management.

**OBJECTIVES •** After reading this chapter, you should be able to:

12-1. Define key terms introduced in this chapter.
12-2. Explain the purposes and goals of performing a scene size-up on every EMS call.
12-3. Given a scenario, identify key findings in the scene size-up related to:
   a. Taking Standard Precautions
   b. Identifying possible scene hazards
   c. Identifying the mechanism of injury or nature of illness
   d. Determining the number of patients
   e. Determining the need for additional resources
12-4. Describe the dynamic nature of scenes and scene size-up.
12-5. Utilize dispatch information and information determined on arrival at the scene to assess scene safety.
12-6. Discuss types of situations that may require a call for additional or specialized resources.
12-7. Describe scenes you are likely to encounter and points to consider before entering such scenes, including crash scenes, other rescue scenes, crime scenes, and barroom scenes as well as potential hazards in approaching any vehicle and its passengers.
12-8. Discuss measures necessary to protect the patient, protect bystanders, control the scene, and maintain situation awareness.
12-10. Discuss factors involved in determining the nature of the illness.
12-11. Discuss factors involved in determining the number of patients.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- index of suspicion p. 304
- mechanism of injury (MOI) p. 304
- medical p. 304
- nature of the illness (NOI) p. 307
- personal protective equipment (PPE) p. 295
- scene safety p. 296
- scene size-up p. 294
- trauma p. 304
Case Study

The Dispatch
EMS Unit 104—respond to an emergency at 68 Chicago Avenue—unknown problem—time out 2316 hours.

Upon Arrival
As you approach the street, you shut off the siren and the emergency lights to reduce the attention that you will draw. Your partner, EMT McKeown, is identifying the addresses out loud, “56, 58, 64, 66.” As she shines a spotlight on a run-down house with a front door standing open, you can barely see the number 68. Your partner calls out, “Hey, where are the lights? The whole house is pitch black.”

How would you proceed at this scene?
During this chapter, you will learn about the special considerations of scene size-up. Later, we will return to this case and apply the procedures you have studied.

INTRODUCTION
The prehospital setting is an uncontrolled environment. An EMT who does not pay close attention to the characteristics of the scene, who fails to follow basic guidelines before entering a scene, and who fails to follow his intuition when things do not seem right runs the risk of serious injury. Many subtle hazards confront EMTs at the scenes of calls. With good sense developed through experience and study, it becomes easier to recognize such hazards. But experience should never lead you to become complacent and let down your guard. The costs of failing to recognize the hazards of an unstable scene can be high for yourself, your partners, and your patients. It is imperative that you identify and pay close attention to the scene size-up characteristics on every call, not just the ones that sound bad. Doing so can save your life.

The scene size-up is the EMT’s initial evaluation of a scene to which he has been called. You have three basic goals during scene size-up:

1. Identify possible hazards at the scene and ensure the safety of yourself and other members of your EMS crew, the patient, and the bystanders.
2. Identify what led to your being called to the scene—either an injury or a medical problem. This identification will determine the steps you follow in patient assessment and emergency care.
3. Determine whether any factors, such as the number of patients or unusual characteristics of the scene, might require a call for additional assistance.

With these goals in mind, you will proceed with the scene size-up by evaluating the following components in a stepwise manner:

1. Take the necessary Standard Precautions (body substance isolation) to protect yourself against contact with blood and other body fluids, and put on any other necessary personal protective equipment:
   - Gloves
   - Eye protection
   - Surgical mask
   - High-efficiency particulate air (HEPA) or N-95 mask
   - Gown
   - Helmet
   - Turnout gear
2. Evaluate the scene for safety hazards (environmental, hazardous materials, violence, roadway traffic, power lines):
   - If the scene is not safe, do not enter until it is made safe.
   - Protect yourself, your crew, the patient, and bystanders.
   - Retreat if necessary if the scene becomes unsafe.
3. Determine the mechanism of injury or the nature of the illness:
   - Is the patient injured (a trauma patient)? ill (a medical patient)? both injured and ill?
   - Determine the mechanism of injury (MOI) for a trauma patient.
   - Determine the nature of the illness (NOI) for a medical patient.
   - Is the MOI or NOI unknown at this time and unable to be determined until further assessment is done?
4. Determine the number of patients at the scene.
5. Determine the need for additional resources to effectively manage the scene or the patient:
   - Additional EMS units
   - Law enforcement
   - Fire department
   - Hazardous materials team for chemical and biological threats
• Special rescue teams (swift water, high altitude)
• Specialized search and extrication teams (structural collapse)
• Power or utility company

Always remember that the scene size-up is a dynamic and ongoing process that continues throughout the call. Scene size-up does not end once you make contact with the patient. Also, only those who are specifically trained should wear the specialized equipment and attempt a specialized rescue.

**TAKE THE NECESSARY STANDARD PRECAUTIONS AND OTHER PERSONAL PROTECTION PRECAUTIONS**

The first goal of the scene size-up is to ensure the safety of the responding EMTs. As you learned in Chapter 2, “Workforce Safety and Wellness of the EMT,” you must consider contact with all body fluids to be a true safety hazard. Appropriate Standard Precautions will definitely reduce your risk of contracting an infectious disease in the prehospital setting. What follows are some key points to remember as you prepare for and perform the scene size-up.

Because the prehospital setting is so uncontrolled, unexpected exposures to blood and body fluids may often occur. **Gloves must be considered standard protective equipment.** Wear examination gloves for every contact with the patient. Also, only those who are specifically trained should wear the specialized equipment and attempt a specialized rescue.

Dispatch information can be incomplete or inaccurate. You will have to make your own assessment of the scene and the need for additional protection. Prior to arriving on the scene, you must anticipate what Standard Precautions and other personal protection is necessary. Any type of equipment that you put on to reduce your risk of personal injury or illness is referred to as **personal protective equipment (PPE).** This may range from simple examination gloves to complex breathing apparatus and suits used in a toxic environment. In addition to Standard Precautions, it is necessary for all EMTs to recognize the need for additional PPE, such as a helmet, puncture-proof or leather gloves, steel-toe boots, turnout gear or other heat-resistant outerwear, high-angle rescue gear, or specialized breathing apparatus, depending on the situation. You should not use any PPE for which you have not been specially trained in its use. As an example, you should not use a self-contained breathing apparatus (SCBA) to enter a confined space with a low-oxygen environment unless you have been specifically trained in the use of the SCBA and have been approved to use it on scene.

As a general rule, the EMT should use the same level of personal protection that is required of other personnel on the scene and in the immediate environment. For instance, if you respond to a factory and every factory worker is required to wear eye protection and a hard hat, you should not enter the scene without eye protection and a helmet. Recognize, however, that some personal protective equipment that is needed in the hazardous zone may not be necessary outside of that area. As an example, a firefighter will wear full protective equipment to enter the burning structure to rescue a patient. The firefighter, still wearing full protective equipment, may deliver that patient to you in a staged area well away from any danger from the structure fire. Since you are working in a safe and protected area, not in the immediate hazard zone, it is not necessary to wear the same full protective equipment as the firefighter.

Consider a different situation, where firefighters or those responsible for extrication at the scene of a crashed vehicle with exposed jagged metal and glass are wearing personal protective equipment to protect against personal injury, which may include turnout gear, helmet, heavy gloves, reflective vest, and eye protection (Figure 12-1). Prior to entering the crashed vehicle to assess and manage a patient, you must consider what level of personal protection is needed to protect yourself.

**FIGURE 12-1** Firefighters wearing full protective gear at the scene of a motor vehicle crash. (© Edward T. Dickinson, MD)
against the same personal injury. Your PPE should be at
the same level of the other rescuers on scene, because
you are in the same immediate hazard zone and ex-
posed to the same hazards.

It is unfortunate that some EMTs do not have the
proper protective equipment available to them or do
not practice proper personal protection beyond Stan-
dard Precautions and may be injured unnecessarily at
a scene.

**DETERMINE SCENE SAFETY**

Once standard and PPE precautions have been taken,
the primary goal of EMTs upon arrival at a scene to
which they have been dispatched is **scene safety**. This
means assessment of a scene to ensure the well-being
of the EMTs, their patient or patients, and any bystanders.

The process of ensuring scene safety is dynamic and
ongoing. It is not done quickly upon arrival at the scene
and then forgotten. The EMT must adjust his actions and
precautions as additional information becomes avail-
able. Information gained from assessment of the scene
is applied throughout the response—through the en-
counter with the patient, treatment, transportation, and,
ultimately, delivery of the patient to the hospital. You
must think scene safety on every call, whether the scene
is a street corner riot or the bedroom of an elderly pa-
tient who has fallen. Be alert at all times.

Scene safety requires that the EMT exercise leader-
ship and take control of the scene. If he fails to do so,
the scene will control the EMT. Someone has to be in
charge. That “someone” might become the patient, a
family member, or a crowd of bystanders if the EMT
fails to take charge.

Sleeplessness, preoccupation with other problems,
apathy, and overconfidence can lead an EMT to shortcut
or ignore the principles of scene safety. Don’t let this
happen to you. The consequences can be costly for the
patient, your partners, and you.

**Consider Dispatch Information**

The process of ensuring scene safety should begin well
before the EMTs arrive at the actual scene. It should start
upon receipt of the call notification from the dispatcher.
The dispatch information can help you anticipate what
Standard Precautions and other personal protection
equipment you will need at the scene.

However, the dispatch information is only a start-
ing point. It is critical to remember that dispatchers may
not have complete and accurate information to work
with. The person calling to report an accident may have
hung up before giving details. The person calling may
fail to recognize a medical condition that would require
increased precautions.

Be aware, too, that callers at times may deliberately
give inaccurate information. For example, a caller may
report chest pains when the problem actually is a stab-
boring or a gunshot wound. If the caller had reported the
facts, it is likely that law enforcement personnel as well
as EMTs would have been dispatched, something the
caller wished to avoid.

Dispatch information can have other, unintended
effects on EMTs. Consider the following sets of calls:

- **Unit 102**, respond to a call at 223 Garfield Street, re-
  ports of shots fired, man down in the street.
- **Unit 107**, caller now reports wires down and arcing
  at the accident scene. Fire and power companies
  en route. Use caution.
- **Unit 101**, proceed to I-80 at the scales. State Patrol
  reports accident with multiple injuries involving
  tanker truck. Be advised, tanker is leaking un-
  known product.

Calls of this nature automatically alert the EMT to be
cautious. They highlight an obvious risk that must be dealt
with. With such calls, EMTs—from those on their first run
to seasoned veterans—automatically begin to think of
their safety at the scene. Such calls indicate that assistance
from police, fire, power company, additional medical per-
sonnel, or other resources will be necessary. The reaction
to the following calls, however, may be different:

- **Unit 105**, respond to 6776 Quail Hollow Drive for a
  67-year-old male with chest pain.
- **Unit 101**, you have an unknown problem at Dr. Smith’s
  office, 2225 Greenbriar Drive.

Calls such as these appear to be routine. The voice
of the dispatcher lacks the urgency that might be dis-
played in the earlier types of calls. The routine nature
of these calls may also lull the responding EMTs into a
lesser state of readiness. Ironically, these “routine” calls
may present a greater threat than the “major” incidents
first discussed. The patient may have been involved in
a domestic dispute. Or family members may become
hostile during the call. Or the patient may have an in-
fected disease that can be transmitted to the EMTs. Or
the patient may have inhaled toxic fumes that are still
present and dangerous at the scene. Or, as noted earlier,
the “chest pain” patient may actually have a stabbing
or a gunshot wound. If the EMTs don’t consider scene
safety on the way to a call, they will expose themselves
to increased danger and possible injury.

Remember, use the dispatch information to prepare
for the scene, but remain alert to the possibility of very
different circumstances upon your arrival.

**Consider the Need for Additional
or Specialized Resources**

At any time during the scene size-up it may be necessary
to recognize your own limitations and call for additional
resources or specially trained personnel for situations or
rescues that are beyond your training. As an example,
it may be necessary to request a hazardous materials
team to respond to a scene involving a chemical exposure. The team may wear encapsulated suits and use specialized equipment and procedures to rescue and decontaminate the patient. Not doing so may put you, your partner, and other personnel at the scene at considerable risk of exposure. Other examples of rescues that may require specialized equipment and personnel include difficult or complicated extrication, high-altitude emergencies, deep diving emergencies, structural collapse, swift water rescues, and high-angle rescues.

**Consider Scene Characteristics**

Personal protection of the EMT is of primary importance. An injured or helpless EMT cannot provide emergency care to a patient. In addition, attention and resources may be diverted from the patient to the injured EMT, risking further compromise to the patient.

You must study the scene carefully and determine if it is safe to approach the patient. This determination must be made on all responses, but different scenes will present different characteristics to consider (EMT Skills 12-1). Your final determination must be tailored to the specific scene, keeping these overriding principles in mind:

- Do not enter unstable crash scenes.
- Managing patients at crash scenes or on roadways and highways places the EMT at extreme risk of being struck by moving traffic.
- Take extra precautions at crime scenes, suspected crime scenes, and scenes involving volatile crowd situations; wait for the arrival of police or, if a scene turns threatening, retreat and wait for the police.
- Be sure to bring your portable radio with you when you leave the ambulance so you can contact dispatch or medical direction from the scene for needed resources or advice.
- Call for help from the appropriate agencies—police, fire department, rescue squad, utility company, water rescue squad, hazmat team, or other—if a scene is outside your area of training or expertise.
- Remove yourself if a scene turns hazardous.

Scenes you are likely to encounter and points to consider before entering those scenes are discussed next.

**Crash Scenes**

At a crash scene, the EMT’s attention is drawn naturally and immediately to the patient or patients. This may put the EMT at considerable risk if the crash scene is not properly controlled and safety precautions have not been taken to protect emergency medical and other personnel—not only from hazards that exist because of the crash itself but also from vehicle traffic around the crash scene.

Before exiting the ambulance and approaching the scene or patients, the EMT must assess the total crash scene. This includes the areas to the left, right, front, back, top, and bottom of the vehicles involved. The boundaries of the accident scene can be limited to a single vehicle or can extend for hundreds of feet in multiple-vehicle or high-speed crashes. When assessing a crash scene, pay particular attention to the points in the following list. For more detailed information on crash scenes, see Chapter 43, “Gaining Access and Patient Extrication.”

- Is the vehicle stable?
- If not, can you safely make it stable or are additional personnel and equipment necessary?
- Are power lines involved (Figure 12-2)?
  - Consider all power lines to be energized until a power company representative tells you they are not.
  - Power lines can be on the car, under the car, or touching a guardrail or wire fence that the car is in contact with.
  - The lines may be lying on wet ground and energizing a large area.
- Does jagged metal or broken glass pose a threat?
  - Can such material be avoided, covered, or otherwise isolated to minimize the threat?
- Are there air bags that have not deployed in the crash?
- Is there fuel leaking and, if so, is there an ignition source nearby?
- Is there fire?
  - If so, has the fire department been called?
  - If rescue is possible, do not approach a burning vehicle directly from the front or the rear, where fire or explosion hazards are greatest, but from the side.
- Are there hazardous materials involved?

**Protecting Yourself and Others at the Crash Scene from Being Struck by Traffic.** Another serious threat to emergency medical and other rescue personnel at a crash scene is moving traffic. There are many well-documented incidents of EMTs being killed or severely injured by vehicles crashing into emergency personnel and emergency vehicles at a crash scene on a highway or roadway. You must always remain alert and take as
many precautions as necessary to reduce your risk of being struck by moving traffic.

Guidelines for working in or near traffic will be discussed in more detail in Chapter 42, “Ambulance Operations and Air Medical Response.” Some general rules to reduce the incidence of being struck are:

- Limit your time on scene to reduce your exposure to traffic.
- Shut down traffic on the roadway if necessary to ensure your safety.
- Place flares or cones far enough from the crash scene to give oncoming traffic plenty of warning of the crash scene.
- Place apparatus and vehicles strategically so they protect the scene.
- Wear bright safety reflective clothing or a vest at the crash scene to make yourself highly visible both day and night.
- Do as much work as possible away from and out of the traffic flow.
- Don’t turn your back to moving traffic.
- Don’t jump highway dividers to provide emergency care while leaving yourself extremely exposed to moving traffic.
- Reduce any unnecessary scene lighting that may distract or impair visibility of oncoming traffic.
- Turn the wheels of the parked emergency vehicles so they are pointed away from the scene.
- Avoid stopping and standing between vehicles.

**Other Rescue Scenes**

Some rescue scenes require specialized training and equipment. The EMT must be prepared to call on additional specialized resources to ensure not only his own well-being but also the successful rescue of the patient. *It is the EMT’s duty to ensure that adequate numbers of appropriately trained and equipped personnel are summoned if necessary to handle special rescues.* Examples of rescue scenes where specialized training and equipment must be considered include the following:

- Chemical, biological, and nuclear weapons of mass destruction
- Heights (rooftops, trees, catwalks, construction areas)
- Natural disasters (e.g., tornadoes, hurricanes, floods)
- Underground areas (caves, manholes, trenches, excavations)
- Collapses/cave-ins (buildings, construction sites, excavations)
- Storage tanks/vats (regardless of contents)
- Silos/bins (suffocation hazards, regardless of contents)
- Farm equipment (This might include equipment such as combines, corn pickers, or augers.)

Some special situations that EMTs might frequently encounter include those described next.

**Unstable Surfaces and Slopes.** Victims of injury or illness may be encountered on unstable surfaces or slopes. Such surfaces create additional difficulties and hazards and can greatly complicate treatment and transport of the patient. Access to patients in such circumstances may require the use of ropes. If you are not trained in the proper use of ropes in such situations, summon or wait for a trained rescue crew. If you have been properly trained, keep the following points in mind:

- Remember to secure the patient to the hillside to prevent him from sliding downslope during assessment, treatment, and stabilization.
- Be sure that vehicles that have gone over embankments have been secured to prevent them from sliding and carrying occupants and EMS personnel away.
- Beware of loose rocks and stones that may be knocked down to your position by rescuers working above.

**Ice.** The presence of ice can complicate any scene, making what would normally be a simple rescue hazardous (Figure 12-3a). Keep the following points in mind:

- Apply sand, salt, or gravel to walks, steps, and roadways where you will be working or over which you will be moving a patient.
• Avoid walking onto frozen ponds, lakes, or other bodies of water if the safety and thickness of the ice is unknown. In these cases, notify rescue teams who are trained and equipped for ice rescue.

• If the ice surface is known to be safe, a tarp, rug, or other portable nonskid surface should be brought to the patient’s side to provide a safe surface from which to stabilize, treat, and prepare the patient for transport.

Water. Drownings are common reasons for the dispatch of an EMT team. But water can also be a factor in other types of calls. Always proceed with caution in situations where water is a factor. See Chapter 25, “Submersion Incidents: Drowning and Diving Emergencies,” for more details. If you are faced with a situation beyond your capacity to handle, summon and wait for backup from those with proper training and equipment.

• Swimming pools—The comparatively controlled environment of a swimming pool presents a major challenge for rescue of a patient. The patient will be visible but, to the EMT who is untrained in water rescue, retrieving the patient will be very difficult and should never be attempted alone. The EMT’s partner should be close at hand to lend assistance, preferably from the pool’s edge. A personal flotation device (life jacket) and a line or pole to assist the rescuer and patient to the pool’s edge should be used.

• Open water—Rescue in open water is a specialized technique that requires training and equipment. The EMT must ensure that adequate resources are summoned to open-water scenes where people have been reported as drowned or missing. If the EMT goes out into the water, he must wear a personal flotation device. Under no circumstances should an EMT wear boots or heavy clothing that can pull him under if he goes into the water.

• Moving water—Rescue in moving water such as rivers, streams, or creeks presents all the problems of open-water rescue further complicated by the force of the current. Often, the current will make swimming difficult if not impossible. Patients and rescuers alike can easily be swept away, even in shallow water, if the current is strong enough. Never wade or walk into moving water in an attempt to effect a rescue without adequate training and equipment. Flooded streams, creeks, and drainage ditches as well as rivers have swept many well-meaning but untrained rescuers to their deaths. Whitewater or moving-water rescues involve specialized techniques and equipment and extensive training (Figure 12-3b). The EMT must ensure that adequate resources are summoned to reports of a drowning or of a person caught in moving water.

Toxic Substances and Low-Oxygen Areas. The EMT must be alert to the possible presence of toxic substances or areas of low oxygen during the scene size-up. Some scenes, such as an accident involving a tanker truck, will present obvious hazards. At other scenes, the hazard may not be as obvious. For example, a call to aid someone who fell in his kitchen might present a toxic hazard if, during the fall, the person knocked over and spilled bleach and ammonia. The combination of the two creates chloramine gas, a lung irritant.

Often, the caller requesting assistance will be unaware that a toxic environment exists. It is your responsibility during the initial scene size-up to determine if the environment is safe. Suspect the presence of toxic substances or an oxygen-depleted atmosphere in the following circumstances:

• A spill, leak, or fire—Scenes that involve highly visible incidents such as tanker spills, pipeline ruptures, and heavy smoke conditions should automatically alert you to call on specialized assistance to control the situation.

• A confined space—Caves, wells, tankers, vats, manholes, sewers, culverts, underground utility vaults, silos, closed garages, and other confined spaces are areas where the EMT must exercise extreme caution. Such areas may be very low in oxygen and/or high in toxic substances such as methane. Entry into a confined space to effect a rescue should be made with appropriate SCBA in place. Many well-meaning rescuers have failed to recognize the risk of confined-space entry and have themselves become victims along with the patients they planned to rescue.

• Multiple patients with similar symptoms—A toxic environment will generally cause all people within it to suffer from similar symptoms. Therefore, the EMT called to a residence in which all occupants, including pets, exhibit similar signs and symptoms must assume that the environment is toxic until it is proven not to be. Faulty furnaces cause such problems every winter. The EMT encountering this situation during the winter months should be prepared to consider the possibility of carbon monoxide poisoning. A blocked flue on a gas hot-water tank can produce the same problem in a closed, air-conditioned residence at the peak of summer.

The EMT must be alert to the possibility of encountering such situations on every call. If the EMT is not trained to make the environment safe in such situations, he must contact specialized rescue or fire units who can. You will learn more about the dangers of these situations and how to cope with them in Chapter 22, “Toxicologic Emergencies” and Chapter 44, “Hazardous Materials.”

Crime Scenes

Chances are good that, as an EMT, you will respond to crime scenes almost as frequently as you will to motor vehicle crashes. Firearms are second only to motor vehicle crashes as a cause of death by trauma. Crime scenes
require special attention to ensure the personal protection of the EMT. Review material about crime scenes in Chapter 2, "Workforce Safety and Wellness of the EMT," for additional information.

Remember that ensuring your own safety is the first step in scene size-up. If you are sent to the scene of a crime, wait for the police to arrive and secure the scene before you attempt to enter. As a general rule, do not enter a known crime scene unless it has been secured by police.

However, there will be times when you are sent to scenes at which no crime has been reported but where you suspect that a crime might be involved. Be alert to the possibility of danger on such calls. A dispatcher may not know that the scene to which he is directing you is, in fact, a crime scene. While you are en route to such a scene, check to see if police have also been called. If they have not, request their support. If you arrive at such a scene and feel uneasy or suspect that a threat might exist, do not enter the scene. Wait for police backup.

On calls to known or possible crime scenes, take the precautions that follow.

Arriving at the Scene. While still several blocks from the scene, turn off the siren and emergency lights. By arriving discreetly, you will draw less attention to the scene and minimize the chances of drawing a crowd. This will give you better conditions in which to perform the scene size-up. If the scene appears too hostile or threatening, do not stop but drive on and await police backup in a secure area.

It is a prudent practice to anticipate the address and to park two to three houses away from the scene. This affords you an additional opportunity to study the scene before becoming involved in it.

At crime scenes in which guns might be involved, parking in such a position will usually put you outside the killing zone. This is defined as the area controlled by hostile fire. If someone inside the house has a gun, an area about 120° in front of the house is at least partially exposed to hostile fire. This area can be much larger depending on the location of the house—for example, one on a corner lot—and on the mobility of the person with the gun. The killing zone is not static and is always subject to change.

Studying the Crowd. If a crowd has gathered before your arrival, assess the crowd. Be aware that the size of the crowd is less important than its mood. Is the scene chaotic? If so, do not allow yourself to be pulled into the chaos. Is the scene hysterical? Again, do not be pulled in. Does the crowd seem hostile to your presence? If it does, your options include retreating until appropriate backup arrives or taking the patient and leaving.

Approaching the Scene. When you have completed your initial evaluation and see no immediate danger, leave the ambulance to approach the scene. Be alert, however, to the possibility that the scene could suddenly turn dangerous. Be prepared to retreat if it does. When approaching the scene, follow these procedures:

- Walk on the grass, not the sidewalk, for a quieter, less obvious approach.
- If you are using a flashlight, hold it beside, not in front of, your body—so that you don’t make your body a possible target (Figure 12-4).
- If you are walking with a partner, walk single file. The last person in line should carry the jump kit (Figure 12-5). This will leave the person or persons at the front of the line unencumbered and better able to react to any problems that may be encountered.
- Only the first person in line should carry a flashlight, because anyone with a flashlight behind the first person will backlight those in front.
- As you approach the scene, make a mental map of possible places of concealment (objects, such as shrubbery, that will hide you) and cover (objects, such as trees, that will both hide you and stop bullets). Keep illuminating or scanning dark or shadowed areas for movement as you approach a house.
• Take a moment to look at windows and corners. If you need to take a longer look, change positions to make it harder for a hostile person to get a fix on you.
• Stand to the side of a door when you knock on it; never in front of it—to avoid being a target for someone shooting, springing out, or reaching to grab at you through the door (Figure 12-6 ■). Standing to the knob side prevents a door that opens outward from blocking you. If the door opens inward, the person opening it will most likely be looking toward the hinge side, letting you see him before he sees you.
• As soon as the door is open, assess the situation before you decide whether to retreat and call for reinforcement or to have your partner move the ambulance up to the front of the building. As you enter, leave doors open behind you to ensure an escape route. Likewise, never appear to block the patient’s route of escape.

At the Patient’s Side. Once you are at the patient’s side, your first priority remains protecting yourself and your partner. The next priority is to protect and treat the patient. If you reach a patient and discover that a crime is, in fact, involved in the situation, be aware that a perpetrator may still be on the scene and police intervention will be necessary. Ensure that the police have been called and follow local protocols. Be ready to retreat.

When you are assisting a patient at a properly secured crime scene, follow these procedures:
• Limit the number of responders at a possible crime scene to the number required to care for the patient.
• Do not allow bystanders to touch or disturb the patient or his immediate surroundings.
• Introduce yourself to the patient carefully and say that you are there to help him. Crime victims are often confused and fearful of contact with strangers.
• Be alert to the possibility that the patient at the crime scene may be not simply a victim but also a perpetrator. Always keep track of the patient’s hands in a hostile situation. Be prepared for the possibility that such a patient may suddenly reach for a weapon.
• If possible, have one EMT keep a constant watch on the bystanders and the surrounding area while you work on the patient—to alert you if a scene begins to turn dangerous.
• Remember as you work on the patient that your task is to render medical assistance and to save his life, not to aid in solving a crime. Be as considerate of police requests as possible, but keep your primary task in mind.
• Where appropriate, assist police in collecting and recording anything on the patient, such as blood, hair, seminal fluid, gunpowder residue, or clothing fibers. Follow local protocol.
• Take extreme care not to disturb any evidence that is not directly on the patient’s body (footprints, soil, broken glass, tire tracks, and so on).
• Never touch or move suspected weapons unless it is absolutely necessary for treating the patient’s injuries. Many guns found are loaded and extremely dangerous to handle because of the possibility of accidental discharge. Such a gun in the hands of an untrained person could pose an extreme hazard to you, your partner, the patient, and bystanders. If you do touch a weapon, do not disturb any fingerprints that may be on it. Pick up a gun by the edge of the grip, and use gauze pads to pick up a knife at the very edge of the blade.
• Wear gloves the entire time on the scene to avoid leaving your fingerprints at the crime scene.
• If you need to tear or cut away clothing to expose a wound, make sure you do not cut through a bullet hole or knife slash in the clothing. Keep the clothing and submit it as evidence to the police.
• If the patient was strangled or tied with a rope or other material, cut at a point away from the knot instead of untangling it—the knot can be used as evidence and may help identify the perpetrator.
• If the patient is responsive, do not burden him with questions about the crime. Treat his injuries and transport him.
• Realize that the patient will probably show extremes of emotion and be prepared to handle them.
• Document who is at the crime scene when you arrive.
• If a patient is obviously dead when you arrive, do nothing and disturb nothing. Summon the police, if they have not already been called, and wait for their arrival. However, remember that you must provide basic life support and other appropriate care, as you would for any patient, unless injuries are so extreme or the patient has obviously been dead for so long that resuscitation is out of the question. Follow your local protocol and standard operating policies and procedures.

Barroom Scenes
Barrooms can quickly become places of danger for EMTs responding to a call. The presence of people consuming alcohol makes any situation volatile and unpredictable.
Scenes in which the patient or bystanders are prone to sudden changes in behavior put the emergency medical personnel at risk for violence and personal injury. The problems are compounded in a barroom, where patrons often know each other and their actions may be affected by long-standing friendships or feuds about which you have no knowledge. In such circumstances, violence can easily erupt, even in what appears to be a routine situation.

Simply entering a barroom can present a special challenge to the EMT. Barrooms are often dark places. If you receive a call to one during daylight hours, your eyes can require several minutes to adjust from bright sunlight to low-light vision. By wearing sunglasses while outside, you can shorten the time of adjustment considerably. You might also keep one eye closed while still outside; this will give the closed eye a marked head start on accommodating to the low light inside the bar.

You will sometimes respond to barroom calls where none of the patrons will be able to tell you what happened to an injured person; often, however, some of them will offer advice on medical treatment. Be patient in such situations. It is critical that you do not antagonize the patrons. A routine question or comment can easily be misunderstood by an inebriated patient or bystander and lead to a violent confrontation.

While working at a barroom call, have your partner stand and survey the patrons at all times. Do not turn your back on the people in the bar. Don’t reply to verbal threats, but never ignore them, either. It only takes an instant for verbal abuse to turn into a physical assault. If the situation becomes threatening, retreat temporarily and call for police support.

**Car Passengers**

Approaching people in vehicles is another seemingly routine situation that can hold unexpected danger for the EMT. The EMT’s uniform or the emergency lights on the ambulance may be misinterpreted as the police by the occupants of a vehicle, who may be intoxicated on alcohol and/or drugs. You should plan the approach to a parked vehicle carefully, following these steps:

- Park the ambulance at least one car-length behind the vehicle. Park with your wheels turned slightly to the left, so that if you have to back up you will not go any deeper into the shoulder of the road.
- Align your headlights in the middle of the trunk of the vehicle, and turn them to high beam. Try to reflect your beams off the rearview mirror, illuminating the car’s interior and also making your approach more difficult for the occupants of the car to see.
- While still in the ambulance, write down the license number of the vehicle and leave it at the radio.
- Note how many people are in the vehicle, their positions, and the driver’s apparent condition. Be wary around tinted windows.
- As you approach the vehicle, be alert to the possibility of other unseen occupants. Check to see if the trunk is locked, and look on the rear seat and the floor as you pass.
- Have your partner open the passenger door a split second before you open the driver’s door; if you are alone, wait for help to arrive.
- Keep behind the center post. Carry an object, such as a report book or bag, that you can throw at the occupant’s face if he becomes violent.
- If you have to retreat, immediately get into your vehicle and back up rapidly. Move 100 to 150 yards to clear the killing zone.

**Protect the Patient**

Ensuring the safety of the patient is an important part of the scene size-up. Accidents and sudden medical emergencies frequently occur in public places or outdoors, away from the patient’s home. Such emergencies expose the patient to a wide range of environmental factors that can cause him discomfort and also contribute to the deterioration of his condition (see Chapter 24, “Environmental Emergencies”). Emergencies can also expose a patient to the curiosity of the public, a situation some may find highly stressful. The EMT must have a keen awareness of how such factors affect the patient and be prepared to do what is necessary to change them in order to ensure the patient’s safety and comfort. If you are unable to control the scene to make it safe for the patient, move the patient quickly to a safer environment, such as in the back of the ambulance.

A victim of a fall onto a sidewalk on a hot, sunny day, for example, can experience extreme discomfort, even burns, from the hot sidewalk. By placing the patient on a backboard as quickly as possible, you can make the patient much more comfortable and may prevent additional injury.

Conversely, the victim of a fall in a wet, slushy parking lot in midwinter faces the risk of hypothermia. This is a potentially life-threatening condition in which the body temperature falls below normal. Providing such a patient with just a blanket is not enough. Major heat loss will occur through the patient’s wet clothing and through the cold, wet surface on which he is lying. Placing such a patient on a backboard as soon as possible will slow heat loss and make him more comfortable. Also, with the patient on a backboard, he may be loaded into the ambulance for the balance of assessment and treatment, minimizing exposure to the elements.

Shade a patient’s face from either the sun or precipitation. This will make him more comfortable and allow you to complete the assessment more easily.

You can protect a patient from the public’s gaze in a way that will also assist you in crowd control. Ask several bystanders to turn their backs to the patient while holding up unfolded bed sheets at shoulder level. The patient appreciates the privacy provided.
The bystanders also become involved in the patient’s care and thus become easier to manage. Such a technique is usually far more effective than sternly telling the crowd to “step back.”

**Protect Bystanders**

Emergencies do draw crowds. Your attention as an EMT must be directed toward the patient. However, the crowd is part of the scene and making sure the bystanders are safe is one of your responsibilities during scene size-up. If hazards to the bystanders cannot be minimized or eliminated, remove the bystanders from the scene.

Keeping the crowd out of the way can be as big a challenge as treating the patient (Figure 12-7 ■). In cases of spills, leaks, fires, or heavy smoke, bystanders must be kept back through the use of roadblocks, detours, police lines, and public address systems advising bystanders of the risk. In such situations, bystanders who do not disperse should be dealt with by the police.

The hazards to the bystanders in smaller-scale emergencies are less dramatic but equally important. A one-car crash can down potentially deadly electrical wires. It can also scatter sharp glass and metal that can cut unwary bystanders. The easiest way of protecting bystanders is to prevent them from getting too close to the scene.

**Control the Scene**

At a scene, it is the responsibility of the EMT to provide for the safety of himself and his partners, his patient, and any bystanders. To carry out these responsibilities, the EMT must sometimes take action to create a workable environment. This can be done through a variety of measures that range from providing more light, to eliminating noise, to moving the patient.

The EMT may need to improve the environment subtly, avoiding a disruption of the scene. For example, a television set may be a source of noise, but turning it off may also eliminate the only source of light in a room. Therefore, if the television’s noise is the interfering factor, turn it down rather than off, or ask that it be turned down. Following is a list of basic measures that you might consider adopting to improve working conditions at a scene:

- **Provide light.** Make it a point to have a good flashlight and keep it handy day and night.
- **Consider moving furniture** that interferes with access to the patient. This should be done after advising the patient or the bystanders of your intentions. In a residence, you must remember that, in spite of the emergency, you are a guest in the home and should demonstrate a proper level of respect toward the owners or occupants. If furniture is moved, it should be moved carefully to avoid any impression of ransacking the room. If possible, attempt to return furniture to its original position before leaving the scene.
- **Consider moving the patient** to an area more conducive to patient care. Attempting to resuscitate a patient in a cramped bathroom would generally make little sense when, by moving the patient 5 feet to the bedroom, you would have plenty of space in which to work. However, whenever an injury is suspected, the patient must be properly immobilized to a backboard before any movement is attempted. Always adapt your actions to the prevailing circumstances.
- **Maintain an escape route** and keep it open when a scene is tense or danger exists. If operating outdoors, try to position the ambulance in such a way that the crowd will not get between you and the patient and the ambulance. When working indoors, consider asking bystanders to keep all doors along the route to the ambulance open. Do not allow yourself to be cornered. If all else fails, remember that windows may be a good emergency escape route.
- **Pay attention to bystanders.** If the mood of a crowd turns ugly, you, your partners, and your patient may be in danger. Remember that a concerned crowd poses far less of a threat than an unruly crowd. Consider involving bystanders in crowd control. If the bystanders are parents or relatives of the patient, a continuing explanation of the measures you are taking will be appropriate.
- **Control the scene** or the scene will control you. Stay in control and anticipate things that will happen before they occur. Initiate action rather than respond to the actions of others at the scene.
- **Stay calm.** Other team members, the patient, and the bystanders will respond more positively.
- **Use tact and diplomacy.** A compassionate, understanding tone may produce more positive results than a harsh, demanding one.
• Be flexible. Have a Plan A to deal with the situation you are facing, but remain ready to shift to Plans B, C, or D if conditions indicate that Plan A won’t work.
• Be open-minded about the situations, circumstances, and conditions you encounter on the job. Prehospital care involves working with people of a variety of ages, races, religions, and backgrounds. Many people have ways of life quite different from yours; some of them are ways that you would not choose to follow. Remember that you have been called to assess, treat, and transport patients, not to judge them.
• Be alert to yourself, your partners, your patient, and your surroundings.
• Be compassionate toward the people you have been called on to serve. Treat all people the way you would wish to have your loved ones treated in their time of need; someday you, too, may be in need.

Maintain Situation Awareness

Scene size-up is a dynamic process. EMS personnel must continuously assess the emergency scene for unusual characteristics such as sounds, smells, or things that look odd. For example, as you are treating a patient who claims to be home all alone, the door of the bedroom opens slightly. That should immediately draw your attention to a potential hazard. It could be the family dog; it might be an open window that blew the door open, or it could be someone who does not want to be recognized behind the door. Whatever it may be, you need to investigate and not leave it to chance that it might be the wind. If the patient is alert and responding appropriately, ask immediately what or who is behind the door. If you are extremely uncomfortable with the situation, you may choose to load the patient immediately and move him to the ambulance. The key to remaining safe is to remain vigilant at all times.

One mistake commonly made by EMS personnel is that once they have performed the initial scene survey for safety hazards, they focus completely on the patient. In essence, they switch from a “scene awareness” to a “patient awareness.” Such a complete transfer of attention to the patient without any recognition of what is happening around you may cause you to be injured or even killed. When at the scene, always maintain a situation awareness. You need to shift your attention to patient assessment and management once you have entered the scene and deemed it safe; however, you still need to be aware of all aspects of the scene around you. To re-emphasize the point, you must maintain a situation awareness.

DETERMINE THE NATURE OF THE PROBLEM

Once scene safety has been ensured, the next step in the scene size-up is determining the nature of the patient’s problem that brought you to the scene. There are two basic categories of problems: trauma and medical. Which category a patient falls into will determine how you proceed with your continuing assessment and treatment of the patient.

Trauma is a physical injury or wound caused by external force or violence. Injuries caused by blunt, penetrating, or blast forces are examples of trauma, as are burns. Such injuries are typically to the skin, muscle, bone, ligaments, tendons, vessels, or organs.

A medical condition is brought on by illness or by substances or by environmental factors that affect the function of the body. A heart attack, a drug overdose, and a case of heat stroke are three examples of medical conditions that you may have to confront.

In prehospital care, the EMT first looks for evidence of an injury. If the possibility of injury is ruled out, the EMT may assume that the patient has a medical condition.

The dispatch information that starts you out on a call will often provide information that can be helpful in categorizing a patient. But, as you have seen, that information can be incomplete or inaccurate. You will have to be alert during the scene size-up for physical clues or other information that will help you understand the nature of the problem.

As always, you should remain open-minded and flexible as you try to determine the nature of the problem. Sometimes a patient will not fit neatly into one category or the other. For example, you may encounter a diabetic suffering from an altered mental status from taking too much insulin who, as a result, has fallen down a flight of stairs. This patient is suffering from both trauma and a medical condition. Similarly, when assessing a trauma patient, you may discover that the patient had a stroke or myocardial infarction. When in doubt, treat the patient as a trauma patient as this will mandate attention to possible spinal injury.

Determine the Mechanism of Injury

When arriving on the scene of a suspected trauma, you will be looking for the mechanism of injury (MOI). Mechanism of injury refers to how the patient was injured. It includes the strength, direction, and nature of the forces that caused the injury. The mechanism of injury is the basis for your index of suspicion. The index of suspicion is the degree of your anticipation that the patient has been injured, or has been injured in a specific way, based on your knowledge that certain mechanisms usually produce certain types of injuries.

The mechanism of injury only provides a degree of suspicion of the types of injuries. It does not, however, provide any indication of the actual injuries or condition. At some point in your career, you will arrive on the scene of a motor vehicle crash where you suspect the driver did not survive or is severely injured based on the condition of the vehicle, only to find the minimally or noninjured driver outside walking around the
scene, smoking a cigarette. On the contrary, you will also arrive on the scene of what appears to be a “fender bender” and find a patient who is critically injured inside the passenger compartment. It is extremely important to use physical examination findings to determine the actual patient injuries and the severity of the condition. Findings such as an altered mental status, elevated heart rate, increased respiratory rate, and pale, cool, and clammy skin are much more important indicators of the patient’s condition and severity than the mechanism of injury.

Identification of the mechanism of injury in a trauma patient may begin with the dispatch information. Dispatch to an automobile crash, a shooting, a fall, or a stabbing will provide some preliminary information as to the mechanism of injury. Once you arrive at the scene, however, it is necessary to take a much closer look at such scene characteristics as damage to the automobile, the use of restraint devices, the distance the patient fell, the type of surface the patient fell on (e.g., grass, carpet, concrete), the position in which the patient landed, the object that struck the patient, or the caliber of the gun the patient was shot with. Such characteristics provide clues to what forces were applied to the body and the possible patterns of injury that may have resulted from them.

Common situations that should create a high index of suspicion for trauma injuries include the following:

- Falls
- Motor vehicle crashes
- Motorcycle crashes
- Recreational vehicle crashes (snowmobile, all-terrain vehicle)
- Contact sports involving intentional or unintentional collision
- Recreational sports (e.g., skiing, diving, basketball)
- Pedestrian collision with a car, bus, truck, bike, or other force
- Blast injuries from an explosion
- Stabbings
- Shootings
- Burns

Chapter 27, “Trauma Overview: The Trauma Patient and the Trauma System,” will provide more details about the nature of injuries resulting from a variety of mechanisms. The following information concerns characteristics you should look for during scene size-up in a number of common situations.

**Falls**

Look for evidence of a fall when arriving on a scene. Fallen ladders, collapsed scaffolding, ropes in a tree or on buildings, trees in the immediate proximity of the patient, stairs, balconies, roofs, and windows are all common places to fall from or indicators that a fall may have occurred. When inspecting the scene of a suspected fall, you will develop a clearer idea of the types of injury the patient may have suffered if you determine the following information:

- Distance the patient fell
- Surface the patient landed on
- Body part that impacted first

**Motor Vehicle Crashes**

Motor vehicle crashes produce some of the most lethal mechanisms of injury (Figure 12-8). Blunt forces applied to the body produce widespread injury to organs, bones, muscles, nerves, and blood vessels. The type of collision or point of impact to the vehicle commonly dictate the types of injuries to expect. Study the vehicle carefully, if possible, to identify this information. Common types of crashes include the following:

- Head-on or frontal collision
- Rear-end collision
- Side or lateral-impact collision
- Rotational impact collision
- Rollover

When approaching the scene of a motor vehicle crash, look for evidence of both external impact to the vehicle from an outside force and internal impact to the vehicle caused by a patient’s body. One EMT should quickly walk around all sides of the vehicle to identify the points of impact. That EMT should also conduct a close inspection of the passenger compartment for signs of impact that correlate with specific types of injury.

The following are significant external signs of vehicle impact to look for and document:

- Deformity to the vehicle greater than 20 inches
- Intrusion into the passenger compartment
- Displacement of a vehicle axle
- Rollover
The following are significant signs of patient impact in the passenger compartment to look for and document:

- Impact marks on the windshield caused by the patient’s head
- Missing rearview mirror
- Collapsed steering wheel
- Broken seat
- Side-door damage
- Cracked or smashed dashboard
- Deformed pedals
- Use of restraint devices and deployment of air bags

Deployment of driver and front seat passenger air bags may produce an impact mark that resembles what would be made by the patient’s head contacting the windshield. In this case, determine if the safety belt restraint system was used and examine the head for evidence of trauma. A restrained patient with no evidence of trauma to the head likely did not impact the windshield.

Ejection from the vehicle usually produces significant blunt or penetrating trauma. Patients often die not from the ejection itself, but from the car rolling on top of them.

The death or significant injury of one passenger should cause you to suspect significant injury to other passengers.

Motorcycle Crashes

Try to determine and document the type of impact involved in the crash of a motorcycle. The following types of impacts are common:

- Head-on—The rider is propelled forward off the motorcycle.
- Angular impact—The rider strikes an object.
- Ejection—The rider is thrown from the motorcycle and impacts the ground, the object involved in the collision, or both.
- “Laying the bike down”—The rider purposefully lays the bike down on its side to avoid another, potentially more serious impact.

It is important to determine and document whether the patient was wearing a helmet. The use of a helmet may prevent or reduce the severity of head injury.

Recreational Vehicle Crashes

Snowmobiles, also known as snow machines, and all-terrain vehicles (ATVs) are commonly operated on uneven terrain, a factor that contributes to rollovers. Crush-type injuries are common. Snowmobiles can travel at high speed, producing severe impact upon collision with trees, rocks, or other vehicles.

With these vehicles be especially alert for “clothesline”-type injuries. In these injuries, a rider is pulled off the vehicle by a low branch, wire, rope, or other low-hanging object. Severe trauma to the neck and airway is common with this type of crash.

Penetrating Trauma

Whenever you receive reports of a shooting or stabbing at the scene of a call, it is necessary to expose and assess the patient’s body to confirm or rule out a stabbing or a gunshot wound (Figure 12-9 ■). With an unresponsive patient, completely expose him and look for a penetrating injury, whether or not blood is visible at the scene or around the body. Be sure to log roll the patient to inspect the posterior body for open wounds. Heavy coats, dark clothing, poor lighting, dark environments, or dark hair hide blood very well. You must inspect the body carefully for open wounds. Open wounds to the chest may not produce much bleeding but can be lethal if not immediately identified and managed.

Blast Injuries

Explosions are another source of trauma. Gasoline, fireworks, natural gas, propane, acetylene, grain dust in grain elevators, and criminal intent are common causes of explosion. Look for injuries caused by the pressure wave associated with the blast, by flying debris, and by the collision that results when a patient propelled by the blast comes into contact with the ground or with other objects. Note also that burns are common at blast scenes.
Determine the Nature of the Illness

In a patient who is not injured but is suffering from a medical condition, you will begin to determine the nature of the illness (NOI) during scene size-up. The patient, relatives, bystanders, or physical evidence at the scene may provide you with clues to determine what the patient is suffering from. You are not attempting to diagnose the patient’s illness. You are gathering information that will narrow down the nature of the patient’s complaint.

The initial information provided by the dispatcher can provide you with some preliminary clues. For example, the dispatcher may transmit, “Respond to a 77-year-old female complaining of chest pain.” You can use such information to help you focus your questioning when you arrive at the scene. As usual, be alert to the possibility that information given to and relayed by the dispatcher is incomplete or inaccurate.

Once you arrive at the scene, you must determine the reason that you were called. Simply asking the patient, family members, or bystanders an open-ended question like, “What seems to be the problem today?” could provide you with the exact nature of the illness. Even if that does not happen, you might obtain at least some information that will help determine the nature of the illness.

Be aware, though, that the patient or his family may try to mislead you or to cloud the real nature of the illness. For example, use of drugs such as heroin or cocaine is illegal. Therefore, the family of a drug-overdose patient may claim they do not know why the patient is unresponsive. They may deny any drug use by the patient if directly asked. They may or may not eventually tell the truth regarding the real reason for the unresponsiveness.

Inspect the scene for clues about the illness. Look for prescription and nonprescription medications, drugs, drug paraphernalia, alcohol, and other pertinent clues. Home oxygen equipment may indicate a preexisting respiratory disease or cardiac condition; thus, you would likely suspect complaints of chest pain or difficulty breathing associated with either condition.

The physical position and condition of the patient may provide information about the illness. A tripod position—sitting up and leaning forward—may indicate respiratory distress or cardiac compromise. Patients with respiratory distress rarely lie flat unless they are completely exhausted. A patient lying very still with his legs drawn up to his chest is likely suffering from severe abdominal pain. A fruity odor emanating from the patient may indicate a diabetic condition. Look for loss of bowel or bladder control, which may have resulted from a seizure or stroke.

Environmental conditions may provide clues to the nature of the illness. Extreme cold, wet and cold clothing, or a patient found outdoors in cool weather should suggest the possibility of hypothermia (low body temperature). A hot and humid environment, especially if the patient was playing a sport or performing some other strenuous activity, should suggest a possible heat emergency. Wooded areas may make you suspect snakebites or spider bites. Bites and stings from marine life are a real possibility if the patient is found at the beach. Scuba equipment should heighten your suspicion that the patient may be suffering a condition brought on while diving. If more than one person complains of similar symptoms in a home, consider the possibility of poisoning from carbon monoxide or some other gas.

The key to this phase of scene size-up is to study both the scene and the patient carefully as you look for clues that increase your suspicion of a particular nature of illness. Remember to write down your findings. Your report will provide emergency department personnel with valuable information that might not be otherwise available, especially if the patient is unresponsive.

DETERMINE THE NUMBER OF PATIENTS

The last major element of the scene size-up is determining the total number of patients. Sometimes this may be simple, as in the case of a single, responsive patient who has called for help because of chest pain. At other times, as in the case of a multiple-vehicle accident during a nighttime snowstorm or a suspected carbon monoxide poisoning in a multifamily dwelling, it may be more complicated.

If you discover that conditions at a scene are beyond your ability to handle, call for additional resources. Such resources may include law enforcement, fire, rescue, or utility company personnel; a hazardous materials team; or an additional basic life support unit or advanced life support team.

If, after studying the scene, you determine that there are more patients than your unit can effectively handle, initiate your local multiple-casualty plan. Follow local protocols in doing so. Such incidents will be covered in Chapter 45, “Multiple-Casualty Incidents and Incident Management.”

Try to make any call for additional assistance before making contact with patients. Once you have made patient contact, you are likely to be completely focused on patient needs and not call for additional help.

If the number of patients surpasses your resources, begin triage and prioritization of patients. If you and your partner can manage the scene and the patients, consider spinal precautions based on the mechanism of injury, proceed with the assessment, and provide emergency care.

It is important to recognize when a scene cannot be adequately controlled. It may be impossible to gain scene control when the crowd is extremely hostile, the family is emotionally charged or upset, threats are being made toward you, or the scene is unstable because of the risk of fire, explosion, or other hazards. You must consider your own safety when working in an uncontrolled environment. If the scene remains uncontrolled, it is best to move as rapidly as possible to remove yourself and the patient from the scene and/or to call for additional resources as needed.

SUMMARY

Scene size-up involves an initial evaluation of the scene. This is considered the first component of the patient assessment because the scene size-up can provide evidence as to whether the patient is injured or ill. If injured, the scene size-up may provide clues as to the mechanism and the potential severity of the injury. This information will dictate what type of assessment is performed and may lead to changes in the initial emergency care provided to the patient.

The goals of the scene size-up are to ensure the safety of those at the scene, to use the characteristics of the scene to determine whether the patient is a trauma patient or medical patient, and to request additional resources as early as possible. The components of the scene size-up are to take the necessary personal protection precautions to include Standard Precautions and other personal protective equipment (PPE), to evaluate the scene for safety hazards, to determine the mechanism of injury or nature of the illness, to establish the number of patients at the scene, and to ascertain and request additional resources to effectively manage the scene or patient(s).

Case Study Follow-up

Scene Size-up

You have been dispatched to an unknown problem. As you approach the street, you shut off the siren and the emergency lights. Pulling up to the house, you notice that 68 Chicago is completely dark. No lights are noted outside or inside the house. Your partner instructs you to proceed past the scene and park two houses up the street.

Because the house is completely dark and there appears to be no activity in it or around it, you contact dispatch and inquire if they have a call-back number. Dispatch responds, “EMS Unit 104, be advised, the call came from 71 Chicago. The patient at 68 Chicago has no phone.” You look out and see that 71 Chicago is well lit. You then request, “Dispatch, can you call back the number for 71 Chicago and verify that this is a legitimate call?” A short time later dispatch contacts you, indicating that the woman at 71 Chicago said the man from 68 Chicago came to her house, said he had an emergency, and asked her to call 911. You contact dispatch and advise, “We are going to approach the scene. Please give us a radio check-up in 2 minutes.”

Before leaving the ambulance, you turn on all the scene lights and focus the floodlight on the front door. You and your partner, EMT McKeown, exit the ambulance after agreeing that you will carry the flashlight while she brings the equipment from the ambulance. You take the lead and approach the house, holding your flashlight out in front of you and to the side. McKeown follows about 8 feet behind with the jump kit. You walk up the front steps and approach the door. McKeown stays at the bottom of the steps watching the rest of the house and your back. You stand to the knob side of the door and knock. An older man opens the door and says nothing, but motions you in. You enter the house cautiously, on the alert for threats or hazards. After you are inside, McKeown enters, taking care to leave the door open behind her.

The man tells you he is Mr. Ziegler. He leads you to the living room where you find an elderly woman lying on the couch. He says, “My wife isn’t feeling well,” and sits in an armchair. You contact dispatch on your portable radio and indicate that you are okay and on the scene.

The room seems neat but sparsely furnished. The only light comes from a small television set. The rest of the house is completely dark. McKeown reaches for the light on the end table and Mr. Ziegler advises her, “The fuses blew. Nothing works but the TV. It’s on batteries.” McKeown walks over to the TV set and you tell her, “Just turn the volume down and leave the TV on. We need the light.”

As you approach the patient, you notice a bottle of the medication Diabenase, used in treating diabetes, on a table next to the couch. Mrs. Ziegler looks up at you and says, “My legs are swollen. They’ve been like this all week.”

McKeown is watching your back and the rest of the room. The scene seems secure. You note no mechanism of injury. Mrs. Ziegler appears to be suffering from a medical condition. There are no other patients to worry about at the scene. You can now begin to assess and provide treatment to the patient.

Patient Assessment

Having determined during scene size-up that Mrs. Ziegler is a medical patient with no signs of trauma, you proceed with the steps of patient assessment care as appropriate for a medical patient. You check for life-threatening conditions and find none. Her mental status, airway, respiration, oxygenation, and circulation are all normal. When you ask, “Why did you call the ambulance today?”

continued
Mrs. Ziegler states that she figured the emergency department wouldn’t be busy on a Monday night. As you continue to ask questions to get her medical history, she confirms that she has diabetes controlled by Glucaphage. The physical exam confirms that her legs are swollen but reveals no other problems. Her vital signs are normal.

You prepare Mrs. Ziegler for transport, positioning her on the stretcher in a sitting position, which she finds comfortable. En route to the hospital you continue to check on her condition and speak with her reassuringly. Mr. Ziegler rides along up front beside EMT McKeown, who is driving.

You contact the emergency department and give a brief report. You transfer Mrs. Ziegler’s care to the nurse in the emergency department following an oral report. You write your prehospital report and prepare the ambulance for the next call. You contact dispatch and mark back in service.

Upon return to the emergency department on another call 3 hours later, you inquire about Mrs. Ziegler. The nurse states she was okay and released about an hour ago. The next-door neighbor came to pick up Mr. and Mrs. Ziegler and take them home.

IN REVIEW

1. Define and list three goals of the scene size-up.
2. List basic guidelines an EMT should follow at potentially dangerous or unstable scenes.
3. List guidelines to follow to protect the EMT from moving traffic at a crash scene or while managing patients on a highway or roadway.
4. Explain the special problems an EMT is likely to encounter in confined areas like a cave, well, or sewer.
5. Explain how EMTs should approach a house that they feel may be the scene of a crime.
6. Explain the chief determination about the nature of the patient’s problem an EMT should make during the scene size-up.
7. Define mechanism of injury.
8. List clues to mechanism of injury that the EMT should be alert to at an automobile crash.
9. List clues at a scene that might indicate the nature of a patient’s illness.
10. Explain why the EMT must determine the total number of patients at a call during the scene size-up.

CRITICAL THINKING

You are dispatched for a possible shooting at a residence. The communications officer informs you, once you are en route, that a 26-year-old female patient has been shot in the abdomen. As you respond to the scene, you begin to formulate your scene size-up plan.

1. What Standard Precautions do you anticipate?
2. What indicators will you look for to determine if the scene is safe to enter?
3. What criteria will you use to categorize the patient as trauma or medical?
4. How will you determine if more than one patient is present on the scene?
5. What other resources may be needed at the scene?
6. When will you call for the additional resources if they are needed?
Patient Assessment

CHAPTER 13

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • **Assessment** (Content Areas: Scene Size-up; Primary Assessment; History Taking; Secondary Assessment; Monitoring Devices; Reassessment)

**COMPETENCY** • Applies scene information and patient assessment findings (scene size-up, primary and secondary assessment, patient history, and reassessment) to guide emergency management.

**OBJECTIVES** • After reading this chapter, you should be able to:

13-1. Define key terms introduced in this chapter.
13-2. Explain the importance of developing a systematic patient assessment routine and list the four main components of the patient assessment.
13-3. List the steps of the scene size-up.
13-4. State the main purpose of the primary assessment and list the components of the primary assessment.
13-5. Explain how forming and revising a general impression of the patient spans the entire patient assessment process.
13-6. Determine if a patient is injured or ill and obtain the chief complaint.
13-7. Identify immediate life threats during the general impression.
13-8. Given a variety of patient scenarios, differentiate those who do and do not need spinal stabilization, demonstrate how to establish in-line stabilization, and demonstrate patient positioning for assessment.
13-9. Using the AVPU method, assess and document the level of responsiveness.
13-10. Determine airway status in responsive patients and those with an altered mental status, demonstrate methods of establishing and maintaining an open airway, and recognize indications of partial airway occlusion.
13-11. Assess the rate and quality of breathing; determine if the patient has absent, inadequate, or adequate breathing; provide positive pressure ventilation in the patient with absent or inadequate breathing.
13-12. Assess oxygenation as determined by the SpO₂ level in the patient who is breathing adequately.
13-13. Assess the circulation to include assessing the pulse, identifying and controlling major bleeding, and assessing perfusion through skin color, temperature, and condition and capillary refill, and recognize and begin treatment for shock.
13-14. Discuss establishing patient priorities by evaluating critical findings to the airway, breathing, or circulation to determine if a patient is unstable and a candidate for rapid secondary assessment and immediate transport to the hospital.
13-15. Describe performing the secondary assessment using an anatomical approach, including steps for assessing the following:
   a. Head
   b. Neck
   c. Chest
   d. Abdomen
   e. Pelvis
   f. Lower extremities
   g. Upper extremities
   h. Posterior body
13-17. Summarize assessment of the vital signs during the secondary assessment.
13-18. Discuss obtaining a history during the secondary assessment, including use of the SAMPLE and OPQRST mnemonics.
13-19. List the sequence in which the steps of the secondary assessment are generally performed for a trauma patient and define the following types of physical exam that can be chosen for a trauma patient:
   a. Rapid secondary assessment for a trauma patient
   b. Modified secondary assessment for a trauma patient
13-20. List the mechanisms of injury that have a high incidence of producing critical trauma and the special considerations for infants and children.
13-21. For the trauma patient with a significant mechanism of injury, discuss how to continue spinal stabilization, reasons to consider requesting advanced life support, and reasons to reconsider transport decisions.

13-22. Explain how to use the Glasgow Coma Scale (GCS) to rank the patient's level of consciousness and how to interpret the resulting GCS score.

13-23. Discuss how to conduct a rapid secondary assessment for a trauma patient with significant mechanism of injury, altered mental status, multiple injuries, or critical finding (unstable patient).

13-24. Discuss critical (unstable) findings, possibilities, and emergency care for the trauma patient associated with assessment of the head, neck, chest, abdomen, pelvis, extremities, posterior body, or baseline vital signs.

13-25. Explain the purpose and elements of the trauma score.

13-26. Discuss how to conduct a modified secondary assessment for a trauma patient with no significant mechanism of injury, altered mental status, multiple injuries, or critical finding (stable patient).

13-27. Explain circumstances when you should perform a complete, rather than a modified, secondary assessment on a trauma patient with no significant mechanism of injury.

13-28. Name the key differences in the secondary assessment for the responsive medical patient versus the unresponsive medical patient with regard to:
   a. Sequence of steps
   b. Appropriate type of physical exam (modified or rapid)

13-29. Explain how to conduct a secondary assessment for a medical patient who is not alert or is disoriented, is responding only to verbal or painful stimuli, or is unresponsive.

13-30. Discuss critical (unstable) findings, possibilities, and emergency care for the medical patient with an altered mental status associated with assessment of the head, neck, chest, or pelvic region.

13-31. Explain how to conduct a secondary assessment for a medical patient who is alert and oriented.

13-32. Explain the purposes of reassessment.

13-33. Explain how to conduct and to complete the reassessment.

**OVERVIEW** • This chapter on patient assessment is divided into four parts. The chapter parts begin on the pages listed here.

**Part 1** Scene Size-Up—page 313
**Part 2** Primary Assessment—page 314
**Part 3** Secondary Assessment—page 332
**Part 4** Reassessment—page 377

---

**Case Study**

During your shift as an EMT, you are called to two different kinds of cases. The first call is to a patient who has been injured—a trauma patient. The second is to a patient who is suffering from a medical problem.

**CALL ONE—A TRAUMA PATIENT**

**The Dispatch**
EMS Unit 74—respond to Newton Drive, Greenway Apartments, Building 24. Unresponsive patient with an unknown problem. Be advised police are at the scene. Time out is 1512 hours.

Upon Arrival
Upon arrival, you find an adult male patient lying supine at the bottom of a two-story fire-escape ladder. The police are on the scene and indicate that they were called for a domestic incident and the neighbors heard fighting and gunshots.

How would you proceed with the assessment of this patient?

**CALL TWO—A MEDICAL PATIENT**

**The Dispatch**
EMS Unit 74—respond to 33 East Sassafras Street. Patient with an unknown problem. Patient’s daughter made the call. Time out is 1623 hours.

continued
**INTRODUCTION**

An EMT’s most important functions are assessing the patient plus providing emergency care and transport to a medical facility. Of these functions, performing an accurate and reliable assessment is the most important, because all of your decisions about care and transport will be based on it.

It is very important that you develop a systematic assessment routine. This will ensure that you assess every patient consistently and appropriately, based on the nature of that patient’s illness or injury. This systematic approach to patient assessment will become second nature as you apply it to each patient, whether that patient’s condition is minor or critical. Without this systematic approach, you are far more likely to become distracted or to develop tunnel vision. For example, the horror of a gory abdominal evisceration might tempt you to immediately begin treating the wound and cause you to delay more critical tasks such as ensuring an open airway or providing needed assisted ventilations.

In this chapter, you will learn about the components of the patient assessment—scene size-up, primary assessment, secondary assessment, and reassessment—that you will perform on every patient you encounter as an EMT.

---

**Part 1 SCENE SIZE-UP**

The first component of patient assessment is the scene size-up. The scene size-up is a dynamic process that continues throughout the entire call. Much of the scene size-up is operational, such as ensuring scene safety and ascertaining the need for additional resources. However, determining the mechanism of injury or nature of the illness and determining the number of patients actually constitute the beginning of the patient assessment process. As you learned in Chapter 12, the phases of the scene size-up are as listed here:

1. **Scene Size-up**
2. **Primary Assessment**
3. **Secondary Assessment**
   - Trauma Patient
   - Medical Patient
4. **Reassessment**

**Steps of the Scene Size-up**

1. Take necessary Standard Precautions.
2. Evaluate scene hazards and ensure scene safety. 
   - Personal protection
   - Protection of the patient
   - Protection of bystanders
3. Determine the mechanism of injury or the nature of the illness.
   - Trauma patient
   - Medical patient
4. Establish the number of patients.
5. Ascertain the need for additional resources to manage the scene or the patient(s).
Once you have ensured that the scene is safe and has been controlled, you are prepared to begin the primary assessment. A primary assessment is conducted on every patient regardless of the mechanism of injury or nature of the illness.

A number of the overall purposes of patient assessment are served—in whole or in part—during the primary assessment: determining whether the patient is injured or ill, identifying and managing immediately life-threatening conditions, and determining priorities for further assessment and care on the scene versus immediate transport with assessment and care to continue en route.

The main purpose of the primary assessment is to identify and manage immediately life-threatening conditions to the airway, breathing, oxygenation, or circulation. During the primary assessment, you will quickly form a general impression of the patient and assess the patient’s level of consciousness (mental status), airway, breathing, oxygenation, and circulation. Any life-threatening condition that is identified must be treated immediately as found—before moving on to the next portion of the primary assessment. As a result of the primary assessment, you will make decisions about priorities for further assessment, care, and transport.

The steps of the primary assessment allow a systematic but not a required linear approach to assessment for, and control of, life threats. It is vital that you progress through the steps of the primary assessment first, and do not allow dramatic but non-life-threatening injuries or conditions to cloud your priorities. For example, a fractured humerus that is protruding through the skin is a dramatic injury. However, the fracture will not immediately cause the death of the patient unless it is associated with major bleeding. By contrast, a patient with clotted blood in the mouth causing the airway to be blocked is in immediate danger. The blood in the mouth is not as dramatic and could easily be missed by an EMT who is not systematically performing the primary assessment. Systematically following the steps of the primary assessment will keep you focused and allow you to identify and correct immediately life-threatening injuries or conditions.

The components of primary assessment are:

<table>
<thead>
<tr>
<th>Components of the Primary Assessment</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Form a general impression of the patient.</td>
</tr>
<tr>
<td>2. Assess the level of consciousness (mental status).</td>
</tr>
<tr>
<td>3. Assess the airway.</td>
</tr>
<tr>
<td>4. Assess breathing.</td>
</tr>
<tr>
<td>5. Assess oxygenation.</td>
</tr>
<tr>
<td>7. Establish patient priorities.</td>
</tr>
</tbody>
</table>

Although the components of the primary assessment are often carried out with the general impression first, followed by assessment of the level of consciousness, airway, breathing, oxygenation, and circulation, it doesn’t have to occur in this linear sequence for every patient. If you approach a patient with a spurting arterial bleed, you will proceed immediately to controlling the immediate life threat to the circulation before assessing the airway, breathing, or oxygenation. Once direct pressure is applied to the bleeding artery, you will go back to assessment of the airway, breathing, and oxygenation. The key to primary assessment is making sure to assess and manage any immediate life threats to the airway, breathing, oxygenation, and circulation during the first 60 seconds after encountering the patient. The order of taking these actions is less important and is based on obvious presenting immediate life threats.

You should be able to conduct this assessment (shown in more detail in Figure 13-1) in about 60 seconds, unless confronted with life-threatening problems that must be treated immediately as found.
Steps of the primary assessment.
FORM A GENERAL IMPRESSION OF THE PATIENT

Primary assessment begins as soon as you approach the patient, allowing you to gain your firsthand impression of the patient.

As you gain experience as an EMT, you will become more adept at gaining valuable information about your patient from your first impressions. For example, if this information has not already been provided to you by dispatch, Emergency Medical Responders, or bystanders, you will immediately observe the patient’s general age (for example, child, adult, elderly) and sex, which may have a bearing on the patient’s condition or care.

You will often be able to gain a quick impression, just from the patient’s general appearance, as to whether the patient seems well or ill, is possibly stable or unstable, or appears to have been injured. A patient who greets you at the door, talks in full sentences, and does not appear to be in much distress would provide a quick initial impression of being stable; whereas, the patient who is alert but appears to be in distress may be potentially unstable (Figures 13-2a and 13-2b). A patient who is bleeding excessively and appears to have a decreased mental status or is extremely pale, or one who appears to be unconscious upon your arrival would cause you to immediately consider him unstable (Figures 13-2c and 13-2d). What the patient tells you about what is wrong with him (the chief complaint) and the items or conditions you notice in the patient’s immediate environment are additional elements of the general impression you form as you approach and make your first contact with the patient (Table 13-1).

![Figure 13-2](a) An alert patient with no obvious signs of illness or injury. (b) A patient exhibiting signs of respiratory distress. (c) A responsive patient with an obvious leg injury. (d) An unresponsive patient who is likely suffering from a medical condition but for whom trauma cannot yet be ruled out.
If a mechanism of injury that you have identified is severe enough to cause you to suspect spinal injury, you will take immediate steps to stabilize the patient’s head and spine. Often you will recognize a life-threatening problem, such as severe bleeding, right away. If you do, you will treat that condition immediately.

Although you form your general impression quickly as you approach the patient, even before you can begin a systematic assessment, the general impression can provide valuable information and often allow you to perform lifesaving procedures without delay.

A general impression can continue to be formed even after the first approach to the patient. In some patients, it is difficult to immediately determine if they are a medical or trauma patient or both. Your general impression and categorization of the patient may change as you collect more information from the scene and patient. Patients who are found in unusual environments or circumstances are sometimes difficult to immediately categorize as medical or trauma, especially those who are intoxicated, are under the influence of drugs, or have psychiatric disorders (Figure 13-3 ■). Be alert for general clues to the patient’s condition or history throughout the assessment (Figure 13-4 ■).

**Determine If the Patient Is Injured or Ill**

As you form your general impression at the beginning of the primary assessment, categorize the patient as injured or ill (a trauma patient) or ill (a medical patient) (Figure 13-5 ■). You will often confirm information already gathered from the dispatcher, scene size-up, First Responders, and bystanders. This determination is important in the next step of assessment.

There are two types of trauma: penetrating and blunt-force. **Penetrating trauma** is a force that pierces the skin and body tissues, often from gunshots and knives but

---

**TABLE 13-1 Forming a General Impression**

- Estimate the patient’s age.
- Note the patient’s sex.
- Determine if the patient is a trauma or medical patient.
- Obtain the patient’s chief complaint.
- Identify (and manage) immediate life threats.
also sometimes from screwdrivers, ice picks, handlebars, broken glass, metal, wood, or any other sharp object.

**Blunt trauma** is caused by a force that impacts or is applied to the body but is not sharp enough to penetrate it. Blunt trauma usually results from blows (as in vehicle crashes, falls, and fights) or from crushing (as in a building collapse or when an extremity gets caught in machinery). Clues to the mechanism of injury may be present in the patient’s immediate environment, for example, a dent in the dashboard, the presence of a bloody knife, or a heavy object that appears to have fallen on the patient.

On the other hand, the environment may offer clues that the patient is suffering not from trauma but from a medical problem. For example, a bottle of nitroglycerin pills may indicate he was having chest pain prior to your arrival. A patient in bed in pajamas at 2:00 in the afternoon may have been sick all day. A pillow next to the bed may make you suspect the patient has been vomiting. An elderly patient lying on the floor of a chilly house may be suffering from hypothermia (a lowered body temperature). Information from the environment can be valuable, especially when the patient is unresponsive.

### Obtain the Chief Complaint

The **chief complaint** is the patient’s answer to the question “Why did you call EMS today?” If the patient is unable to answer, the chief complaint may be the response of the family member or bystander who placed the emergency call. If no one can provide an answer, the chief complaint may be what you infer from observation.

The chief complaint may regard pain (“My stomach hurts”), abnormal function (slurred speech), a change in function from normal (“She doesn’t seem to be herself”), or an observation made by you (bizarre behavior indicating a possible psychiatric problem). The chief complaint is quickly ascertained during the general impression.

Do not always assume that the original complaint is the true chief complaint. In a patient who is injured, you may think the chief complaint is obvious. You might suspect the pain associated with an obviously crushed and deformed leg to be the chief complaint. However, if the patient also states, “My chest is killing me,” you must immediately suspect a possible chest injury or heart condition, which are potentially more serious than an extremity injury, and focus assessment on the patient’s chest.

A trauma patient may have an observable chief complaint—for example, a wound. Medical conditions, rarely offer such obvious signs. So obtaining the chief complaint from a medical patient is extremely important.

Ask additional questions that refine a broad chief complaint, such as generalized abdominal pain. Suppose through further questioning you determine that the patient has been complaining of the same pain for the past 2 years. You must then ask, “Why did you call EMS today?” This will tend to focus the patient on what has changed to make him more concerned. He may now state, “This morning I vomited bright red blood.” The chief complaint has changed and has set the tone for further assessment and emergency care.

In unresponsive patients, the chief complaint may need to be established through family, friends, or bystanders at the scene or from the environment itself. Ask, “Can you tell me what happened?” and “Was the patient complaining of anything before he became unconscious?” Do not assume that the bystander at the scene understands what unconsciousness truly means. You may need to ask, “Did the patient respond in any way when you were talking to him?”

If there is a possible life threat, the chief complaint, along with scene size-up, will help determine priorities for further assessment, care, and transport. You would opt for immediate transport following the primary and secondary assessments, with further assessment continuing en route. For a less serious complaint, you would proceed with assessment and emergency care on scene before transporting the patient.

### Identify Immediate Life Threats During the General Impression

If you identify an obvious life-threatening condition during the general impression phase as you begin to assess the patient, you must immediately treat it. For example, you arrive at the scene of an injury incurred during a domestic dispute. After ensuring that the scene is safe, you enter. From the doorway, you spot a stab wound to the patient’s left lateral chest. Since an open wound to the chest is an immediate life threat, you immediately place your gloved hand over the wound until your partner can prepare and apply the appropriate dressing. Only then do you continue with the primary assessment, watching especially for other injuries related to the stabbing. Obvious immediate life threats are those that you identify as you approach the patient—without having to look or feel for the problem. There are few obvious life threats that you would stop the primary assessment to manage. Life threats that require immediate management if found during the general impression are listed in Table 13-2.

The American Heart Association guidelines of 2010 emphasize the need to quickly recognize cardiac arrest and immediately begin chest compressions. Thus, the intervention sequence in the cardiac arrest patient has changed from ABC to CAB: immediate initiation of chest compressions followed by opening the airway and providing ventilation, along with AED application. It is also recognized that many of the interventions can be accomplished simultaneously with enough EMTs or emergency medical personnel on the scene. It is extremely important to reinforce that upon recognition of cardiac arrest the resuscitation must begin immediately with chest compressions. During the resuscitation, the EMT must ensure minimal interruption of
chest compressions while providing other interventions or assessments.

If the patient appears to be unresponsive, with no breathing or no normal breathing (gasiing or agonal breaths), quickly assess the carotid pulse in the adult and child, brachial pulse in the infant (no more than 10 seconds). If no signs of life are present, immediately begin chest compressions. Apply the AED as soon as it is available without interruption to chest compressions until the AED indicates a “stand clear” or analysis of the rhythm. Follow the AED prompts. Also, delay ventilation until after the first set of compressions is delivered.

Establish In-Line Stabilization

If you determine or suspect that the patient has been injured, ask yourself if the mechanism of injury could have been significant enough to injure the spine. (Do not automatically rule out possible spinal injury in patients who are ill. Consider a diabetic patient who is found unconscious at the bottom of a stairway.)

If you suspect a possible spinal injury based solely on the mechanism of injury, you must manually stabilize the patient’s spine before other assessment or care. Take manual in-line stabilization by bringing the patient’s head into a neutral in-line position and holding it there. The procedure (Figure 13-6) is:

1. Place one hand on each side of the patient’s head.
2. Gently bring the head into a position in which the nose is in line with the patient’s navel.
3. Position the head neutrally so the head is not extended (tipped backward) or flexed (tipped forward).

It is possible to have a stable injury of the vertebrae in which the spinal cord has not been damaged. If immediate and proper manual in-line stabilization is not accomplished, however, the vertebral injury may become unstable as a result of the patient moving or being moved. For example, you and your partner grasp the patient by the

**TABLE 13-2 Immediate Life Threats That May Be Obvious During the General Impression**

The following are life threats that require immediate management if found during formation of the general impression:

- An airway that is compromised by blood, vomitus, secretions, the tongue, bone, teeth, or other substances or objects
- Obvious open wounds to the chest
- Paradoxical movement of a segment of the chest (inward movement on inhalation and outward movement on exhalation)
- Major bleeding (steady flow or spurting)
- Unresponsive with no breathing or no normal breathing (agonal or gasping breaths)

Thus, having a high index of suspicion and recognizing the need for proper spinal stabilization is extremely important prior to and during the primary assessment.

Once manual in-line stabilization is established, it must be maintained, even after a cervical spinal immobilization collar (CSIC) is applied, until the patient is completely immobilized to a backboard with backboard straps and a head immobilization device. Complete spinal immobilization will be discussed in Chapter 32.

**Position the Patient for Assessment**

If you find the patient prone (face down), it is necessary to quickly log roll him into a supine position (face up) (EMT Skills 13-1). It is not possible to properly assess the airway and breathing with the patient prone. Prior to log rolling the patient, quickly assess the posterior thorax and lumbar regions, the vertebral column, buttocks, and posterior aspects of the lower extremities by inspecting and palpating for any major bleeding, deformities, open wounds, bruises, burns, tenderness, or swelling. If an open wound to the posterior thorax is present, quickly occlude the wound with a nonporous or occlusive dressing taped on three sides prior to log rolling the patient into a supine position. If spinal injury is possible, establish in-line stabilization before log rolling.

**ASSESS LEVEL OF CONSCIOUSNESS (MENTAL STATUS)**

Indicate to the patient that you are an emergency medical technician and you are there to help. In the trauma patient, do this only after taking manual in-line stabilization to avoid any unnecessary movements by the patient. Quickly determine if the patient is awake, if he responds to a stimulus, or if he is unresponsive.
Assess the Level of Responsiveness

The patient’s level of responsiveness can be rapidly assessed by using the AVPU mnemonic (Table 13-3).

Make adjustments in gauging the mental status of an infant or young child. Note whether the child is following movements with his eyes. Crying may replace speech as a response. For response to verbal stimulus, watch and listen for the child’s reaction to a shout. The response to painful stimulus should be similar to an adult’s.

Alertness and Orientation

If the patient’s eyes are open and he is able to speak as you approach him, you would assume that the patient is alert. However, a patient can be alert but agitated, confused, or disoriented. If the patient is not alert, proceed to check his response to verbal stimulus.

Responsiveness to Verbal Stimulus

If the patient opens his eyes and responds or makes an attempt to respond only when you speak to him, he is responsive to verbal stimulus. If the patient does not speak, quickly check to determine if he will obey your commands. Instruct the patient to “squeeze my fingers” or “wiggle your toes.” If the patient obeys the commands, you can assume he has a higher level of responsiveness than the patient who stares off, talks inappropriately, mumbles incomprehensibly, or does nothing at all.

Responsiveness to Painful Stimulus

If there is no response when you speak to the patient, you should try a painful stimulus. Painful stimulus is just that: applying pain to the patient to determine if and how he responds. Painful stimuli can be applied either centrally or peripherally. A central painful stimulus is applied to the core of the body. The following are methods of applying central painful stimuli (Figures 13-7a to 13-7d):

- **Trapezius pinch.** Pinch the trapezius muscle that extends from along the base of the neck to the shoulder.

<table>
<thead>
<tr>

</tr>
<tr>
<td>• P Responds to Painful Stimulus</td>
<td>• U Unresponsive</td>
</tr>
</tbody>
</table>

**FIGURE 13-7** Methods of applying painful stimuli include (a) a trapezius pinch, (b) supraorbital pressure, (c) a sternal rub, (d) an earlobe pinch.
Grasp 1 to 2 inches of the trapezius muscle and squeeze the muscle. Be sure that you have the muscle and not just the skin.

- **Supraorbital pressure.** Slide your finger under the upper ridge of the eye socket and apply upward pressure. Be careful not to produce any damage to the eyelid or globe during this procedure.
- **Sternal rub.** Apply hard downward pressure to the center of the sternum with the knuckles of your hand.
- **Earlobe pinch.** Pinch the soft tissue portion of the earlobe.
- **Armpit pinch.** Pinch the skin and underlying tissue along the margin of the armpit.

Peripheral painful stimuli can be applied; however, you must use caution in interpreting the results of the test. Common peripheral painful stimuli include:

- **Nail bed pressure.** Apply point pressure to the cuticle portion of the nail bed.
- **Pinch to the web between thumb and index finger.**
- **Pinch to the finger, toe, hand, or foot.**

To determine if the patient is responding to the painful stimulus, watch his face as well as his body. Look for a facial grimace or any other body movement.

The patient who responds to a painful stimulus typically responds with either purposeful or nonpurposeful movements. The purposeful movements are attempts made by the patient to remove the stimulus or avoid the pain. This could be as significant as the patient grabbing your hand or as insignificant as a small movement away from the pain or a slight upward sweeping motion of the hand. If the patient lifts his arm and makes a purposeful movement toward the painful stimulus as if to push it away, or if he moves his body away from the painful stimulus, you would document this as “withdraws the stimulus” or “withdraws from pain.” If the patient reaches up and grabs your hand, you can be sure the movement is purposeful and that he has a higher level of brain function than the patient who just moves his arm toward the pain.

Patients with a head injury or those with spinal cord injuries may respond to a painful stimulus but may not respond appropriately or normally. The patient with a spinal cord injury may only respond to pain applied above the site of the injury or to pain on only one side of the body. Two nonpurposeful movements—that is, having no purpose relative to the painful stimulus—are flexion posturing and extension posturing (Figures 13-8a and 13-8b). In flexion posturing, also known as *decorticate* posturing, the patient arches the back and flexes the arms inward toward the chest. In extension posturing, also known as *decerebrate* posturing, the patient arches the back and extends the arms straight out parallel to the body. Both are signs of serious head injury.

*Figure 13-8* Nonpurposeful movements: (a) flexion (decorticate) posturing, and (b) extension (decerebrate) posturing.

**PATHOPHYSIOLOGY PEARLS**

- Low oxygen levels (hypoxia) cause a patient to be agitated and anxious. High carbon dioxide levels (hypercapnia) cause the patient to become confused and sleepy.

**PATHOPHYSIOLOGY PEARLS**

- Flexion (decorticate) posturing is associated with compression of the brain at the upper portion of the brain stem. Extension (decerebrate) posturing is produced when the lower portion of the brain stem is being compressed. These are signs of serious head injury.

**Problems with Some Types of Painful Stimuli.**

It is important to always assess a central painful stimulus in a patient who is not responding to verbal stimuli. When the nail bed is pinched (a peripheral painful stimulus), the pain impulse travels to the spinal cord. The spinal cord may turn the impulse immediately around and send an impulse back to the muscle to move. The impulse never goes to the brain, so it is not the brain telling the muscle to move but the spinal cord just turning the impulse around and sending it back out again. If you pinch a nail bed on the right hand and the patient moves the right hand, you would want to interpret this as purposeful movement generated by the brain to withdraw from the painful stimulus. However, since this is a
peripheral stimulus, the brain may never have received the stimulus. So interpreting this as purposeful movement would be a false assessment finding and might make you believe the patient’s brain is responding more appropriately than it is. Thus, always be sure to assess a central painful stimulus, which will be transmitted to the brain.

The sternal rub method of applying painful stimulus to a patient has been questioned, because it produces results that may be less specific than the trapezius pinch and supraorbital pressure. When the sternal rub is applied, the patient may move his arm upward. This may be nonpurposeful movement; however, it appears as if the patient is making a movement to withdraw the stimulus, which can be incorrectly interpreted as purposeful. Also, some anecdotal evidence suggests that hard downward sternal pressure must be applied for 30 seconds to get an accurate response from a sternal rub. This may produce bruising and damage to the tissue over the sternum.

**Unresponsiveness**

A patient who does not respond to verbal or painful stimuli is considered to be unresponsive. Unresponsive patients commonly lose their gag and cough reflexes and the ability to control the tongue and epiglottis, often leading to airway compromise. Because unresponsiveness is a significant finding, the unresponsive patient is considered a priority for emergency care and transport.

The patient who is not alert but responds to either verbal or painful stimulus is considered to have an altered mental status. This patient is not completely unresponsive but, like the unresponsive patient, may be prone to airway compromise.

**Document the Level of Responsiveness**

It is important to document the exact response to the stimulus, for example, “The patient groaned and flexed his left arm” or “The patient made a facial grimace and grasped my hand.” A patient who grabs your hand when you apply a painful stimulus versus a patient who has flexion posturing indicates two significantly different levels of cerebral function. Obviously, the patient with the ability to grasp your hand has a much better level of neurological function than the flexion-postured patient; however, both could be placed generally into the category of responding to painful stimulus. The more specific you are regarding how the patient responds, the easier it is for others to assess for a deteriorating mental status at a later point in time.

Assessment of the patient’s mental status should take you no longer than a few seconds to accomplish. Do not waste time performing an extensive neurological exam during the primary assessment. The AVPU check is to quickly establish a baseline for mental status. A much more detailed neurological exam will be performed later in the assessment process.

**ASSESS THE AIRWAY**

Once you have assessed the patient’s level of responsiveness, you must immediately proceed to assessment of the airway (Figure 13-9 ■ if no other obvious immediate life threats are present. A closed or blocked or occluded airway is an immediately life-threatening condition. Your patient will not survive without a patent (open) airway, no matter how diligent your emergency care. You must closely assess the airway and, if it is not patent, immediately open it, using manual techniques and mechanical devices if necessary.

**Determine Airway Status**

The AVPU check of the patient’s level of responsiveness can be used to quickly rule out a possible airway problem. A patient who is alert, responsive, and talking without signs of distress can be assumed to have a patent airway. Thus, the mental status check is a helpful tool for simultaneously gathering information about airway status.

**In the Responsive Patient**

If the patient is alert and talking without difficulty, or if the infant or child is crying, you can assume the airway is patent and move on to the assessment of breathing. However, an alert patient who has stridor on inspiration or exhalation or who is having difficulty in speaking, gasping between words, using extremely short sentences, or not talking at all should be examined closely for a blocked or partially blocked airway or for other causes of respiratory distress. If you have any doubt that the airway is open, you should immediately take the necessary steps to open it (as will be described).

**In the Unresponsive or Severely Altered Mental Status Patient**

Unresponsive patients or patients with a severely altered mental status, such as those only responding to painful

![Assess the airway. To open the airway, use the jaw-thrust maneuver for a trauma patient. Use the head-tilt, chin-lift maneuver for a medical patient.](https://www.bradybooks.com)
stimuli with flexion or extension, have a high incidence of airway occlusion resulting from relaxation of the muscles in the upper airway. The muscle relaxation allows the tongue and epiglottis to fall back and partially block the lower part of the pharynx and the opening to the trachea. In this situation, use the techniques described next to open or to maintain an open airway.

Open the Airway

If the patient is not talking or responding normally, has a severely altered mental status, or is unresponsive, assume that the airway is or may become closed. You must immediately open the airway and take measures to maintain the airway’s patency.

The airway is opened and maintained by using, as needed, any or all of the following techniques:

- Manual airway maneuvers to prevent the tongue and epiglottis from blocking the airway: the head-tilt, chin-lift maneuver or the jaw-thrust maneuver.
- Suction and/or finger sweeps to remove blood, vomitus, food, secretions, or foreign objects.
- Airway adjuncts to maintain a patent airway: the oropharyngeal airway or the nasopharyngeal airway.
- Manual thrusts to the abdomen (Heimlich maneuver), or a combination of chest thrusts and back blows for infants to force bursts of air from the lungs—used to relieve a blockage of the airway by a foreign body that cannot be relieved by any of the techniques already listed.
- Positioning of the medical patient who has no suspected spinal injury in a modified lateral position (recovery or coma position) to allow secretions, blood, or vomitus to flow out of the mouth instead of into the airway. If the medical patient requires ventilation, he must be maintained in a supine position. It is not possible to effectively ventilate the patient while he is on his side. The patient can be quickly turned on his side if he vomits or has a large amount of secretions and then placed supine again to resume ventilation. Always have suction available in the patient who is unresponsive or who has an altered mental status.

The head-tilt, chin-lift and jaw-thrust maneuvers, suctioning techniques, and the use of airway adjuncts were taught in Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

Table 13-4: Sounds That May Indicate Partial Airway Occlusion

<table>
<thead>
<tr>
<th>Sound</th>
<th>Description</th>

<td>Crowing</td>
<td>A sound like a cawing crow on inspiration</td>
</tr>
<tr>
<td>Stridor</td>
<td>Harsh, high-pitched sound on inspiration</td>
</tr>
</tbody>
</table>

Sounds that frequently indicate partial airway occlusion are listed in Table 13-4 and discussed next.

Snoring

If a snoring (sonorous) sound is heard, it is an indication that the tongue and likely the epiglottis are partially blocking the airway. Use the head-tilt, chin-lift maneuver (if there is no suspicion of spinal injury) or the jaw-thrust maneuver (if spinal injury is possible) to relieve any obstruction of the airway by the tongue. If this does not correct the snoring, insert an oropharyngeal airway (for an unresponsive patient without a gag reflex). If the patient gags when you insert an oropharyngeal airway, remove it immediately, be prepared to suction, and consider insertion of a nasopharyngeal airway.

Gurgling

A gurgling sound is an indication that a liquid substance is in the airway. Immediately open the mouth and suction out the contents. If the contents are too thick to be suctioned, turn the patient on his side and sweep the mouth out with your fingers, a tongue blade, or the suction catheter itself. A patient with possible spinal injury must be log rolled onto his side while manual in-line stabilization is maintained. Be cautious when placing your fingers in a patient’s mouth, even if he is unresponsive. The patient can very easily, and unintentionally, bite down and injure you significantly. Place a bite stick between the teeth if necessary to avoid a patient bite.

Do not waste time when clearing the airway. The key is to be prepared and use whatever device or technique is most readily available that clears the contents so they are not aspirated into the airway, respiratory tract, or lungs.

Crowing and Stridor

Crowing and stridor are both high-pitched sounds produced on inspiration. Both are most commonly associated with the swelling or muscle spasms that result from conditions such as airway infections, allergic reactions, or burns to the upper airway. These conditions typically

Indications of Partial Airway Occlusion

When you approach the patient, you may hear abnormal sounds from the upper airway. These sounds are an indication that the airway may be partially blocked.
cannot be relieved by manual maneuvers, suctioning, or insertion of an airway adjunct.

Inserting anything such as an airway adjunct, suction tip, tongue blade, or fingers into the mouth or throat of a pediatric patient with a suspected upper airway infection can cause extremely dangerous spasm and a complete airway obstruction. Such a patient may complain of a sore throat or hoarseness and typically will be leaning forward with the neck jutted out or drooling. A patient with these signs and symptoms should be suspected of having an upper airway infection. Instead, in these cases, it may be necessary to begin ventilation with a bag-valve-mask device with supplemental oxygen immediately to ensure adequate movement of air past the swollen tissues. For more details on assessing respiratory illnesses, see Chapter 16, “Respiratory Emergencies.”

**ASSESS BREATHING**

As soon as you secure an open airway, assess the patient’s breathing status (Figure 13-10■). The assessment of breathing can only be done after securing an open airway; therefore, this step must always follow opening the airway. Assess to:

- Determine if breathing is adequate or inadequate (Table 13-5).
- Determine the need for early oxygen therapy if breathing is adequate.
- Provide positive pressure ventilation with supplemental oxygen for inadequate breathing.

**Assess Rate and Quality of Breathing**

The best method to assess breathing is by looking, listening, and feeling. When doing so, assess both the amount of air breathed in and out (tidal volume) and the approximate respiratory rate. Remember that one respiration consists of one inhalation and one exhalation.

![FIGURE 13-10](https://www.bradybooks.com)

**TABLE 13-5 Inadequate Breathing Versus Adequate Breathing**

<table>
<thead>
<tr>
<th>Inadequate Breathing</th>
<th>Adequate Breathing</th>
</tr>
</thead>
<tbody>
<tr>
<td>Inadequate rate or inadequate tidal volume</td>
<td>Adequate rate and adequate tidal volume</td>
</tr>
<tr>
<td>= inadequate breathing</td>
<td>= adequate breathing</td>
</tr>
</tbody>
</table>

**Look**

Get down and place your ear and face close to the patient’s nose and mouth while looking at the chest. Look for the following:

- **Inadequate tidal volume.** Poor movement (rise) of the chest wall, indicating that an inadequate amount of air is being breathed in with each respiration. This is typically described as shallow respiration.

- **Abnormal respiratory rate.** Breathing that is either too fast or too slow (outside the ranges of 8–24 per minute for an adult, 15–30 per minute for a child, 25–50 per minute for an infant).

- **Bradypnea.** A respiratory rate that is too slow, called bradypnea, may cause the minute volume (amount of air breathed into the lungs in 1 minute) to be inadequate. Thus, the slow rate will lead to hypoxia (inadequate oxygen delivery to the tissues). The amount of air taken in with each breath may be adequate, but there are not enough breaths to maintain an adequate supply of oxygen to the cells. The breathing rate that would be defined as bradypnea varies with the type of patient. Obviously, adults breathe at slower rates than infants and young children; therefore, a rate that is considered bradypnea in an adult is much slower than a rate that is considered bradypnea in an infant or child. As an example, a respiratory rate of 16 per minute is more than adequate in an adult or older child; however, it may be too slow in an infant.

You must consider the rate with the whole assessment of the patient. Consider the mental status and other signs when determining if the rate is adequate or inadequate. For instance, if a patient has a respiratory rate of 8 per minute and an altered mental status with signs of respiratory insufficiency (retractions, poor air exchange) and hypoxia (agitation, restlessness, cyanosis), you would consider the rate inadequate and begin positive pressure ventilation. Thus, the rate is not considered inadequate unless there are other signs of respiratory insufficiency present.

The following conditions may cause bradypnea (abnormally slow respiratory rates): hypoxia (especially in young children and infants), drug overdose on depressant drugs, head injury, stroke, hypothermia (cold emergency), and toxic inhalation.
**ASSESSMENT TIPS**

Because brain cells require a constant supply of oxygen, an altered mental status may be an early sign of hypoxia (low oxygen levels).

- **Tachypnea.** A respiratory rate that is too fast, called tachypnea, may not always result in better breathing status for the patient. When the rate becomes excessive, the lungs do not have enough time between breaths to fill adequately; therefore, the minute volume (volume of air the patient is breathing in 1 minute) becomes inadequate. The result is inadequate breathing, leading to hypoxia. Keep in mind that a rate that is too fast in an adult may be normal in a young child or infant. As an example, a respiratory rate of 40 per minute in an adult is excessive and may lead to inadequate breathing, whereas a rate of 40 per minute in an infant is considered normal.

**PATHOPHYSIOLOGY PEARLS**

When the respiratory rate is greater than 40 per minute in the adult, the time for the lungs to fill is so short that the tidal volume will become inadequate and the patient will likely become hypoxic.

**ASSESSMENT TIPS**

A rapid respiratory rate should alert you to the possibility that the patient is hypoxic. However, be aware that elderly patients typically have higher resting respiratory rates than younger patients: an average of 20 per minute.

Again, you must view the respiratory rate as one part of the whole patient assessment. If the patient is talking and alert, without distress, the breathing is adequate. However, if the patient has signs and symptoms of inadequate breathing, the rate or depth would be considered ineffective and intervention with positive pressure ventilation would be necessary.

Conditions that may lead to tachypnea (abnormally fast respiratory rates) are hypoxia, fever, pain, drug overdose, stimulant drug use, shock, head injury, chest injury, stroke, and other medical conditions.

**PATHOPHYSIOLOGY PEARLS**

Chemoreceptors constantly measure the amount of carbon dioxide and oxygen in the arterial blood. Carbon dioxide is a strong stimulus to breathe. As its level in the blood increases, the respiratory rate increases in an attempt to eliminate the excess carbon dioxide from the body.

Look for the following additional signs of inadequate breathing:

- **Retractions**—identified by a sunken-in appearance of tissues that are pulled inward on inhalation at any of these locations:
  - the suprasternal notch (above the sternum)
  - intercostal spaces (between the ribs)
  - supraclavicular spaces (above the clavicles)
  - Use of the neck muscles on inhalation
  - Nasal flaring—the nostrils flaring out as the patient inhales
  - Excessive abdominal muscle use
  - Tracheal tugging—pendulum motions of the trachea in the anterior neck during inhalation
  - Pale, cool, clammy skin—a sign of poor perfusion to and oxygenation of the cells and tissues
  - Cyanosis—a bluish or blue-gray tone of the skin seen early around the lips, nose, and fingernail beds indicating inadequate oxygenation
  - A pulse oximeter (SpO₂) reading of less than 95%

**ASSESSMENT TIPS**

Pale, cool, and clammy (moist) skin is an early sign of hypoxia. Cyanosis is a late sign.

Also, quickly observe the patient’s respiratory pattern. Look for:

- Asymmetrical movement of the chest wall—The chest wall should move symmetrically (both sides moving together) and smoothly. Unequal movement—for example, one side moving up and outward as the other moves down and inward—is an indication of a significant chest injury.

**Listen and Feel**

Listen for air movement and feel for escape of warm humidified air. Very little air movement is an indication of inadequate tidal volume and inadequate breathing.

**Absent or Inadequate Breathing**

Not all of the breathing difficulties that you may observe, or that the patient may tell you about, are immediately life threatening. A patient may be experiencing some difficulty in breathing, yet be breathing adequately to support life, at least for the time being.

During the primary assessment, you are observing for signs of absent or inadequate breathing—conditions that are immediately life threatening and that must be treated at once. Life-threatening breathing problems are:

- **Absence of breathing** (apnea). Identified by no chest wall movement and no sensation or sound of air moving in and out of the nose or mouth
- **Inadequate breathing.** Identified by:
  - An insufficient or ineffective respiratory rate
  - Signs of an inadequate tidal volume such as poor chest rise and little air movement from the nose and mouth
• Signs of inadequate oxygenation, such as deteriorating mental status; pale, cool, clammy skin; or cyanosis
• Signs of serious respiratory distress, including difficulty in breathing (dyspnea), poor chest wall movement, retractions, nasal flaring, use of neck muscles during inhalation, and/or poor air exchange from the nose and mouth

**PATHOPHYSIOLOGY PEARLS**

Dyspnea, the uncomfortable sensation of breathing difficulty, is produced when the oxygen demands of the cells are not being met by the respiratory or circulatory system.

If the patient is apneic (not breathing) or is breathing inadequately, you must immediately begin positive pressure ventilation with supplemental oxygen. Any delay in treatment could lead to brain death and cardiac arrest.

As you learned in Chapter 10, "Airway Management, Artificial Ventilation, and Oxygenation," positive pressure ventilation is any method that forces air and oxygen into the patient’s lungs when the patient is unable to breathe adequately, or at all, on his own. It can be achieved by mouth-to-mask, bag-valve-mask device, or a flow-restricted, oxygen-powered ventilation device. Whenever you perform positive pressure ventilation, you need to attach and deliver supplemental oxygen within the first few minutes after beginning ventilation. To ensure a patent airway so that the ventilations reach the patient’s lungs, you should insert an oropharyngeal or nasopharyngeal airway prior to beginning ventilation.

A patient with an insufficient or ineffective breathing rate that is too slow or too fast requires positive pressure ventilation with supplemental oxygen. If an ill or injured patient with a breathing rate greater than 24 per minute is responsive and has an adequate tidal volume, administer oxygen and continually reassess the patient for signs of inadequate breathing.

### Adequate Breathing

If the chest is rising and falling adequately, you hear and feel good air exchange, the respiratory rate is adequate, and no evidence of serious respiratory distress is present, assume that the patient’s breathing is adequate.

If the patient with adequate breathing is responsive, but is ill or injured, consider administering oxygen.

### ASSESS OXYGENATION

After making a determination that the breathing is adequate, you must assess the oxygenation status. This is done by looking for any signs of hypoxia, hypoxemia, poor perfusion, heart failure, or respiratory distress; determining if the patient complains of dyspnea; and by applying a pulse oximeter. The pulse oximeter should be applied early in the assessment process to determine the oxygenation status. The routine application of a nonrebreather mask at 15 lpm to deliver large concentrations of oxygen on every patient regardless of the oxygenation status is no longer recommended.

### Oxygen Therapy in the Patient with Adequate Breathing

In the patient who is breathing adequately, oxygen administration is based on signs and symptoms of hypoxia, hypoxemia, poor perfusion, heart failure, or respiratory distress; complaint of dyspnea; and on the SpO2 reading. As an example, if an alert patient is complaining of abdominal pain and has no signs of hypoxia, hypoxemia, poor perfusion, heart failure, or respiratory distress; has no complaints of dyspnea; and the SpO2 reading is 96% on room air—you can elect not to administer any oxygen at all. If oxygen is to be administered, it is done with a low concentration, usually delivered by a nasal cannula at 2 to 4 lpm and titrated to achieve an SpO2 of 94% or greater. If at any time the patient’s mental status deteriorates; the patient becomes anxious, confused, sleepy, or disoriented; the patient exhibits other signs or symptoms of hypoxia, hypoxemia, poor perfusion, or respiratory distress; the patient complains of shortness of breath; or the SpO2 reading drops below 94%—immediately place the patient on supplemental oxygen.

Always err to benefit the patient, and never withhold oxygen if it is needed. If you do not have a pulse oximeter or an SpO2 reading cannot be obtained, place the patient on supplemental oxygen. If signs of severe hypoxia are present and the patient is breathing adequately, place the patient on a nonrebreather mask at 15 lpm. As you become more experienced, it will become easier to make clinical decisions regarding the extent of oxygen therapy to provide for the patient.

### ASSESSMENT TIPS

The patient with an SpO2 reading of <94% should be considered to be hypoxemic and receive supplemental oxygen.

Once you have assessed and controlled any immediate life threats associated with breathing, and have begun positive pressure ventilation with supplemental oxygen or have considered oxygen therapy, you must quickly progress to assessment of the circulation.

### ASSESS CIRCULATION

An assessment of the circulation includes checking the following (Table 13-6):

- Pulse
- Possible major bleeding
- Skin color, temperature, and condition
- Capillary refill
To assess for a carotid pulse, locate the thyroid cartilage (Adam's apple) and slide your fingers down the neck laterally on the same side on which you are positioned until you feel the groove between the larynx and the bulk of muscles in the neck. The carotid artery is located there and should be felt with the index and middle fingers.

Maintain in-line stabilization when assessing for pulses in a trauma patient. The EMT who is at the patient's head holding in-line stabilization can assess the carotid pulse by sliding the index and middle fingers of one hand down the neck to the correct landmark until feeling the pulse. Do not assess or compress the carotid pulses on both sides of the neck simultaneously as this may reduce circulation and prevent the delivery of oxygen to the brain.

As you learned in Chapter 11, in a patient who is 1 year old or less, it is necessary to palpate a brachial pulse, which is found on the lateral aspect of the upper section of the arm between the biceps and triceps muscles (Figure 13-12).

When palpating the pulses, quickly determine:
- If the pulse is present or not
- The approximate heart rate (beats per minute)
- The regularity and strength

### Assessment of circulation during the primary assessment should occur in this sequence:
- Assess for presence or absence of pulse.
- Assess for possible major bleeding.
- Assess skin color, temperature, and condition.
- Assess capillary refill.

During the primary assessment, the main purposes for checking circulation are to determine whether the heart is beating, whether there is any severe bleeding, and whether blood is circulating adequately (the patient may be suffering from a perfusion problem or shock). A problem in any of these areas is life threatening and must be treated immediately.

### Assess the Pulse

You learned about pulses and how to assess them in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” During the primary assessment, you will not attempt to make a precise reading of heart rate. This will happen later, when you take the vital signs during the secondary assessment. For now, if the patient is unresponsive you first want to ascertain whether the heart is beating. In the adult patient, if you cannot feel a radial pulse (at the wrist), immediately assess for a carotid pulse (in the neck) (Figure 13-11). The carotid pulse is typically the most prominent pulse and is the last to be lost in the patient. A pulse that is growing faint usually can be felt in the carotid artery even when it can no longer be felt in a peripheral artery.

### ASSESSMENT TIPS

Elderly patients commonly have “irregularly irregular” heart rhythms (that is, an irregular, or abnormal, rhythm that has no regular pattern). In many elderly patients, this kind of abnormality is their normal rhythm; however, it is important to report and document this finding since it may be related to their current condition.

When determining approximate heart rate, remember that a more accurate heart rate will be determined later in the patient assessment. During the primary assessment, it is most appropriate to estimate the heart rate as fast, normal, or slow.
Note heart rates that are less than 60 per minute or greater than 100 per minute. Bradycardia, a heart rate less than 60 per minute, may indicate severe hypoxia (oxygen starvation), head injury, drug overdose, heart attack, or some other medical condition. (It is important to remember, however, that athletes and other well-conditioned individuals commonly have heart rates less than 60 bpm at rest.) Bradycardia is an ominous sign of hypoxia in infants and children. Tachycardia, a heart rate greater than 100 per minute, may indicate anxiety, blood loss, shock, abnormal heart rhythms, heart attack, drug overdose, early hypoxia, fever, and other medical or traumatic conditions.

It was once thought that the pulse location could provide an estimate of the systolic blood pressure; however, this method of estimating the systolic pressure has not been supported by the scientific literature. One thing that has been established is that, in order for a pulse to be palpated, the systolic pressure must be at least 60 mmHg. A peripheral (radial, brachial, or femoral) or central (carotid) pulse will likely not be felt with a systolic blood pressure less than 60 mmHg. It is important to determine the quality of the pulse in relation to its location. Peripheral pulses may be weaker and less prominent or absent in hypoperfusion states.

If the carotid pulse is absent, immediately begin chest compressions followed by positive pressure ventilation with supplemental oxygen and application of the automated external defibrillator (AED). (The AED will be covered in detail in Chapter 15, “Shock and Resuscitation.”)

**Identify Major Bleeding**

Scan the body looking for any indication of major bleeding. If you notice large pools of blood or completely blood-soaked clothing, immediately expose the area by cutting away clothing with your scissors (Figures 13-13a and 13-13b). Major bleeding is typically identified as bright red, spurting bleeding (arterial) or dark red, steady, rapid bleeding (venous). If either of these types of major bleeding is present, immediately place gloved fingers or a gloved hand on the wound and apply direct pressure to control the bleeding. Apply a pressure dressing once the bleeding has been controlled. During the primary assessment, do not waste time dealing with slow, oozing capillary bleeding or other wounds that do not present with major bleeding, no matter how dramatic they may appear. The control of bleeding will be covered in detail in Chapter 28, “Bleeding and Soft Tissue Trauma.”

**ASSESSMENT TIPS**

If the patient has lost a significant amount of blood, the arterial bleeding may not be spurting by the time you reach the scene. The loss of blood volume will reduce the pressure to the point that it is no longer great enough to make the blood spurt. Instead, the bleeding will be a steady flow.

**Assess Perfusion**

The patient’s perfusion (the sufficient supply of oxygen to the body’s cells that results from adequate circulation of blood through the capillaries) can be assessed by checking the skin’s color, temperature, and condition (Figure 13-14). Capillary refill is typically a more reliable indicator of perfusion status in infants and children. The assessment of skin was discussed in detail in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.”

**ASSESSMENT TIPS**

Capillary refill alone cannot provide an accurate assessment of perfusion in infants, children, or adults. You must also assess the mental status, heart rate, peripheral and central pulses, skin signs, and blood pressure to determine the perfusion status of the patient.
Cyanotic. Cyanotic, or blue-gray, skin may indicate reduced oxygenation from chest injuries, blood loss, or conditions like pneumonia or pulmonary edema that disrupt gas exchange in the lungs. It is a late sign of poor perfusion.

Skin Color

The skin is normally referred to as pink, even though it doesn’t have a pink color tone. In all patients, including dark-skinned patients, the color can be observed at the mucous membranes of the mouth (including the lips), at the mucous membranes that line the eyelids, under the tongue, and at the nail beds. The nail bed is the least desirable place to check color because cold temperatures, some chronic medical illnesses, smoking, and other conditions may restrict blood flow to the hands and feet.

Because the skin plays a major role in body temperature regulation, it is important to realize the effects of the environment on the skin. You would expect a patient in a cold temperature to present with cooler and more pale-looking skin. A patient in a hot environment would typically have flushed (red), warm skin. With these exceptions, the skin colors listed next are considered to be abnormal.

Skin Temperature

The skin temperature is best assessed by partially taking off your gloves and placing the back of your hand or fingers on the patient’s abdomen, face, or neck. The skin is normally warm to the touch but may instead be hot, cool, or cold.

Assessment Tips

A patient with anemia, who has a low number of red blood cells or low hemoglobin content to start with, may take longer to become cyanotic when hypoxic.

Pathophysiology Pearls

The alpha receptor properties of epinephrine (adrenaline) that circulates in response to shock will cause the vessels in the skin to constrict, shunting the blood away from the vessels in the skin and to the core of the body. Because the warm red blood is no longer in the skin, it will take on a pale appearance and feel cool.

Cyanotic. Cyanotic, or blue-gray, skin may indicate reduced oxygenation from chest injuries, blood loss, or conditions like pneumonia or pulmonary edema that disrupt gas exchange in the lungs. It is a late sign of poor perfusion.

Pathophysiology Pearls

In a cold environment, the vessels in the skin constrict, causing the blood to be shunted to the core of the body to preserve the heat at the core. Because the warm, red blood has been shunted away from the skin, the skin takes on a pale appearance and becomes cool. In a hot environment, the vessels in the skin dilate (increase the diameter) to increase the flow of blood to the skin. This allows the hotter blood to flow to the skin where it can be distributed over a large surface area and cooled by the air and through evaporation of sweat. The flow of hotter blood to the skin may cause the skin to appear flushed and feel warm.

Pale or mottled. Skin that is pale or mottled typically indicates a decrease in perfusion and the onset of shock (hypoperfusion). If the patient’s skin is pale or mottled, suspect that the patient is losing blood internally or externally or suffering another cause of shock.

Pathophysiology Pearls

The hemoglobin in the red blood cells changes color when starved of oxygen, thus giving the skin of a hypoxic patient its bluish (cyanotic) tint.

The skin is normally referred to as pink, even though it doesn’t have a pink color tone. In all patients, including dark-skinned patients, the color can be observed at the mucous membranes of the mouth (including the lips), at the mucous membranes that line the eyelids, under the tongue, and at the nail beds. The nail bed is the least desirable place to check color because cold temperatures, some chronic medical illnesses, smoking, and other conditions may restrict blood flow to the hands and feet.

Pale or mottled. Skin that is pale or mottled typically indicates a decrease in perfusion and the onset of shock (hypoperfusion). If the patient’s skin is pale or mottled, suspect that the patient is losing blood internally or externally or suffering another cause of shock.
drug overdose, or other medical conditions that interfere with the body’s ability to regulate temperature, may result in cool skin.

- **Cold skin.** A patient with frostbite, significant cold exposure, immersion in cold water, or severe hypothermia (general cooling resulting from cold exposure) will have cold skin. The skin may appear to be firm or stiff. This is a significant sign of frostbite or a cold-induced injury.

- **Cool and clammy skin.** Cool skin that is moist is referred to as cool and clammy. It may be related to blood loss, fright, nervousness, anxiety, pain, or other medical conditions. It is the most common sign of shock (hypoperfusion).

### Skin Condition

Skin condition refers to the amount of moisture found on the skin surface. This can be checked during palpation of the skin for temperature. The skin is usually either dry or moist:

- **Dry skin.** A patient who is dehydrated or suffering from severe heat exposure (heat stroke) or from some medical emergencies may have dry skin.

- **Moist skin.** Skin that is moist or wet to the touch may indicate sweating in a hot environment, exercise or exertion, or fever. Moist skin may also be associated with heart attack, hypoglycemia, shock (hypoperfusion), or many other conditions.

### PATHOPHYSIOLOGY PEARLS

Moist, or clammy, skin associated with medical or trauma conditions is typically produced from circulating epinephrine. The alpha stimulant property in the epinephrine stimulates the sweat glands.

Skin temperature, color, and condition will be discussed in more detail in the chapters dealing with specific medical conditions and injuries.

### Capillary Refill

Capillary refill is a quick method to check peripheral perfusion. It is more reliable in infants and children than in adult patients, in whom other influences may provide an inaccurate reading. In adults, depress the nail bed, the fleshy part of the palm along the ulnar margin, the forehead, or the cheeks and release. In children and infants, depress the forearm or over the kneecap (EMT Skills 13-2).

Capillary refill is most reliable when assessed at room temperature. Cold exposure causes a delay in the refill and causes refill time to increase. If the refill of capillaries (a return of the pink color) takes longer than 2 seconds in the infant, child, or adult male at room temperature, tissue perfusion may be inadequate. The upper limit for adult females is 3 seconds and for the elderly is 4 seconds. Thus a capillary refill time at room temperature of greater than 3 seconds in adult females or greater than 4 seconds in the elderly would be considered a “delayed” capillary refill. Once again, capillary refill is only one indicator of many that must be assessed to determine the perfusion status of the patient. Capillary refill alone will not provide an accurate determination of the perfusion status.

### Shock (Hypoperfusion)

Shock (hypoperfusion) is a life-threatening condition. If your primary assessment reveals pale, cool, and clammy skin, especially if there is a significant mechanism of injury, an altered mental status, or severe bleeding, assume that the patient is in shock.

Treatment for shock needs to begin during the primary assessment and continue until the patient is transferred to the medical facility staff. Control any serious bleeding. If possible, splint any bone or joint injuries, but only if it does not delay transport. Provide positive pressure ventilation with supplemental oxygen, if needed, or oxygen at 15 lpm by nonrebreather mask; keep the patient warm; and consider immediate transport with assessment.

### ESTABLISH PATIENT PRIORITIES

In the course of the primary assessment, you should have identified and managed any immediately life-threatening conditions related to the status of the airway, breathing, oxygenation, and circulation. Any critical finding to the airway, breathing, oxygenation, or circulation makes the patient unstable (Table 13-7). During the primary assessment, the airway must be opened. Supplemental oxygen must be administered based on the patient’s signs and symptoms of hypoxia, hypoxemia, poor perfusion, heart failure, complaint of dyspnea, or respiratory distress; or a low SpO2 reading. Inadequate breathing must be managed by positive pressure ventilation with supplemental oxygen. Any major bleeding must be controlled. If the patient is unresponsive, with no breathing (apneic) or no normal breathing, immediately initiate CPR, beginning with chest compressions, and apply the automated external defibrillator (AED). Treatment for shock (hypoperfusion) must be undertaken if the patient displays signs of shock.

At this point in the primary assessment—based on your general impression and your assessment of the patient’s mental status, airway, breathing, oxygenation, and circulation—it is necessary to decide if the patient is unstable and a priority for a rapid secondary assessment and immediate transport or if, instead, the patient is stable and you will continue with the secondary assessment on the scene. For example, the trauma patient who is critically injured and categorized as unstable requires a rapid secondary assessment and immediate transport to
the emergency department with continued assessment and treatment provided in the ambulance, whereas the
injured patient who appears stable should be further as-
\[<br>\]
\[\text{essed and treated at the scene prior to transport. The}
\[<br>\]
\[\text{medical patient could fall into either category—rapid}
\[<br>\]

\[<br>\]
\[\text{the need for a rapid secondary and immediate transport.}
\[<br>\]
\[\text{If your priority decision is for immediate transport,}
\[<br>\]
\[\text{you will first conduct a rapid secondary assessment to}
\[<br>\]
\[\text{identify any additional signs of injury or illness, and to}
\[<br>\]
\[\text{be sure that nothing significant has been overlooked,}
\[<br>\]
\[\text{before the patient is fully immobilized and/or secured}
\[<br>\]
\[\text{to the stretcher. The rapid secondary assessment for}
\[<br>\]
\[\text{trauma or the rapid secondary assessment for the medi-
\[<br>\]
\[\text{cal patient will be explained in detail later in the chapter.}
\[<br>\]
\[\text{The rapid secondary assessment can typically be}
\[<br>\]
\[\text{accomplished in no more than 60 to 90 seconds}
\[<br>\]
A decision for rapid secondary assessment and immediate transport does not mean that a full secondary assessment and appropriate emergency care are not conducted. However, the priority decision you make at the conclusion of the primary assessment will dictate when and where the remainder of the assessment and treatment will occur, whether at the scene or en route to the hospital. Thus, the primary assessment sets the pace for the entire patient encounter.

### Part 3 SECONDARY ASSESSMENT

Once you have conducted the scene size-up and the primary assessment to identify and manage immediately life-threatening conditions involving the airway, breathing, oxygenation, and circulation, your next step is to conduct the secondary assessment to identify any additional injuries or conditions that may also be life threatening.

Further emergency care will be based on the information you gain from the history and physical exam. There are three major steps to the secondary assessment.

### Components of the Secondary Assessment

- Conduct a physical exam.
- Take baseline vital signs.
- Obtain a history.

### TABLE 13-8 Criteria for Which Rapid Transport Is Required

<table>
<thead>
<tr>
<th>Criteria</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>A poor general impression (The patient looks ill or is severely injured. Look for cyanosis, pale skin, significant blood loss, and multiple wounds or injuries to the head, chest, abdomen, pelvis, posterior thorax, or multiple extremities.)</td>
<td>A pulseless patient</td>
</tr>
<tr>
<td>An unresponsive patient or patient with an altered mental status who lacks a gag or cough reflex (This is significant because the patient cannot protect his own airway.)</td>
<td>Uncontrolled hemorrhage or severe blood loss</td>
</tr>
<tr>
<td>A responsive patient who is not obeying commands</td>
<td>A patient with pale, cool, clammy skin who you suspect is in shock (hypoperfusion)</td>
</tr>
<tr>
<td>Inability to establish or maintain a patent airway</td>
<td>A patient with an open wound to the chest or a flail segment</td>
</tr>
<tr>
<td>A patient experiencing difficulty in breathing or who exhibits signs of respiratory distress</td>
<td>Severe chest pain with a systolic blood pressure of less than 100 mmHg</td>
</tr>
<tr>
<td>Absent or inadequate breathing for which the patient requires continuous positive pressure ventilation</td>
<td>Severe pain anywhere</td>
</tr>
<tr>
<td>A poor general impression (The patient looks ill or is severely injured. Look for cyanosis, pale skin, significant blood loss, and multiple wounds or injuries to the head, chest, abdomen, pelvis, posterior thorax, or multiple extremities.)</td>
<td>Complicated childbirth</td>
</tr>
<tr>
<td>An unresponsive patient or patient with an altered mental status who lacks a gag or cough reflex (This is significant because the patient cannot protect his own airway.)</td>
<td>Extremely high body temperature—above 104°F</td>
</tr>
<tr>
<td>A responsive patient who is not obeying commands</td>
<td>Signs of generalized hypothermia</td>
</tr>
<tr>
<td>Inability to establish or maintain a patent airway</td>
<td>Severe allergic reaction</td>
</tr>
<tr>
<td>A patient experiencing difficulty in breathing or who exhibits signs of respiratory distress</td>
<td>Poisoning or overdose of unknown substance</td>
</tr>
</tbody>
</table>
The way these steps are carried out will vary according to the condition of the patient: trauma or medical, responsive or unresponsive, with a serious or a minor complaint.

For example, a patient who has lacerated his shin while operating a weed cutter does not necessarily need a complete head-to-toe exam if you are certain that the injury was isolated to that one anatomical region and involves no underlying organs or body systems. Your physical exam and history will deal primarily with the leg injury. This type of focused exam deals only with isolated injuries where the patient is completely alert, oriented, and has not experienced any mechanism that might result in organ damage or multiple injuries.

Likewise, a medical patient does not need to have his entire body inspected and palpated; however, it is important that you examine all body systems that are potentially related to the medical condition. As an example, a medical patient with no mechanism of injury who is complaining of shortness of breath does not need to have his pelvis and symphysis pubis inspected or palpated. However, it would be important to examine the central nervous system, cardiovascular system, and respiratory system. This would involve examination of the head, neck, chest, abdomen, upper and lower extremities, and posterior body for signs associated with the complaint. Examining only the thorax in this case would cause you to possibly miss a number of other signs and the potential cause of the patient complaint or severity of the condition.

You must tailor your assessment to the needs of the patient and the suspected condition or injury. However, if you have any doubt as to the significance of the mechanism of injury or the illness, or if the potential exists that the patient may have suffered multiple injuries, or if the mental status is altered, err on the side of benefit to the patient and perform a complete secondary assessment from head to toe.

The sequence of the steps of the secondary assessment will depend on whether the patient has suspected injuries or a medical problem and whether the patient is responsive or unresponsive. For example, history taking precedes the physical exam and vital signs for a responsive medical patient for two reasons; (1) the most significant information about a medical condition will usually be obtained from what the patient tells you, and (2) if the patient loses responsiveness, you will have lost the opportunity to get the history, whereas you can conduct the physical exam and obtain vital signs whether the patient is responsive or not.

For a trauma patient, the physical exam and vital signs are done before the history, because the most significant information about injuries will usually come from the physical exam. (When EMT partners are working together, these steps can often be done almost simultaneously, for example, with one partner obtaining the history and taking vital signs while the other does the physical exam.)

Although the physical exam for a trauma patient and for a medical patient are similar, the type of information that you are assessing for may differ. In the trauma patient, the physical exam is conducted to identify evidence of injury. In the medical patient, the physical exam is often conducted to determine the severity of the condition. For example, you will assess the lower extremities for both the trauma patient and the medical patient in most cases, including assessment of distal pulses and motor and sensory function. However, in the trauma patient you are primarily looking for tenderness (pain in response to palpation), swelling, and deformities—in addition to weak or absent pulses or poor motor or sensory function—as an indication of injury. In the medical patient, you may be looking for signs of an inadequate pumping function of the heart, as in a heart attack or congestive heart failure—for example, discoloration of the lower extremities or swelling to the ankles plus poor pulses—or for poor or absent motor and sensory function as a sign of the status of the brain in a suspected stroke patient.

If you are unable to categorize the patient as a trauma or a medical patient by the time you complete the primary assessment, you should continue with a complete head-to-toe secondary assessment to gain additional information to appropriately categorize the patient.

Suppose you are called to the scene for a “man down.” When you arrive on the scene, you find a patient supine on the side of the street. Only one bystander is present who states that she found the patient lying in the street. You have no immediate clues from the dispatcher, scene, or bystander as to the emergency problem. Your general impression and primary assessment of the airway, breathing, oxygenation, and circulation do not provide any clear indications as to whether the patient’s condition has resulted from trauma or a medical cause.

You must suspect that the patient has been hit by a car, shot, assaulted, stabbed, fallen and hit his head, or suffered from some other mechanism of injury. However, you must also suspect that the patient could have had a heart attack or a stroke, has a low blood sugar level, or is suffering from some other medical condition. You would conduct a rapid secondary assessment from head to toe and continue to look for indications of both trauma and medical problems while you continue your emergency care.

EMS runs of this nature require a high index of suspicion on your part and the application of judgment and common sense to the sequence and manner in which you conduct the secondary assessment.

In most cases, you will have determined whether the patient is suffering from trauma or from a medical condition by the time the primary assessment has been completed. For a patient who has been injured, you will continue with a secondary assessment for a trauma patient. A patient who is suffering from a medical condition requires a secondary assessment for a medical patient. These two variations of the secondary assessment (for a trauma patient and for a medical patient) will be discussed.
later in the chapter. In order to perform a secondary assessment on either the trauma or the medical patient, it is important to first learn the components and techniques of the complete secondary assessment. From that foundational information and technique, you will be able to alter the secondary assessment to meet the needs of any particular patient, complaint, condition, or situation.

**OVERVIEW OF SECONDARY ASSESSMENT: ANATOMICAL AND BODY SYSTEMS APPROACHES, BASELINE VITAL SIGNS, AND HISTORY**

Use the techniques of inspection, palpation, and auscultation to identify additional signs, symptoms, and complaints of the patient. Any potential immediate life threats should be managed as found. For example, if an open wound is found on inspection of the chest, it must be immediately managed by placing your gloved hand over the wound and then occluding it with a nonporous or occlusive dressing. Non-life-threatening injuries in the noncritical or stable patient will be noted and treated after the examination, or en route in the critical or unstable patient, if time and the patient’s condition permit.

When conducting the secondary assessment in a stable, noncritical trauma patient, the injuries can be managed as found. If you note swelling and deformity to the lower portion of the left arm, you will closely assess the area, immobilize it, and continue with the assessment. Bone injuries and soft tissue injuries, such as lacerations, abrasions, and punctures, are managed as found during the physical exam in the stable, noncritical trauma patient.

Any clothing that interferes with your ability to properly examine the trauma patient should be cut on the anterior part and allowed to fall away, if this was not already done during the primary assessment. Take modesty into consideration and cover the patient with a sheet.

If any doubt exists as to how extensively to assess the patient, complete the entire secondary assessment. In the critical or unstable patient, conduct a rapid secondary assessment so that you do not divert attention that is required for the ongoing care of life-threatening injuries or medical conditions.

**Performing the Secondary Assessment: An Anatomical Approach**

The secondary assessment should be conducted systematically, starting at the head and moving to the feet (EMT Skills 13-3). A rapid secondary assessment would be conducted to identify life-threatening injuries or conditions in the unstable or critically injured trauma patient or in the unstable or critically ill medical patient. The rapid secondary assessment uses the same techniques as those for the complete secondary assessment illustrated in EMT Skills 13-3 and discussed in this section, but the approach is abbreviated to focus on rapidly finding potential life threats. Thus, the rapid secondary assessment may not use all of the techniques discussed in this section. The rapid secondary assessment for the trauma and medical patient will be discussed later in the chapter.

The trauma patient who has suffered a significant mechanism of injury or who potentially has multiple injuries must be completely exposed at the end of the primary assessment prior to beginning the secondary assessment (Figure 13-15). If the patient is not exposed, you are at a high risk of missing potentially life-threatening injuries. Keep patient modesty and environmental concerns in mind when exposing the patient.

**Assess the Head**

Inspect the head and scalp for any deformities, contusions, abrasions, punctures, burns, lacerations, or swelling (EMT Skills 13-3A). If conducted at the scene on the trauma patient with a spinal injury, maintain spinal stabilization as applied during the primary assessment. If adequate resources are available and the patient has critical findings or is unstable, the patient may be immobilized to the backboard prior to the secondary assessment. Depending on the type of device used and whether the patient is immobilized or not, your access to the head may be limited. Do not remove any immobilization device to further examine the head.

Palpate the entire head. Start at the parietal region (top of the head) and work your way down to the occipital region (back of the head). Palpate the temporal (side) and frontal regions of the skull. Do not poke your fingers into the scalp or skull. Cup your hands...
together and palpate with the palms of the hands. This will reduce the possibility of damage to the brain from inadvertently pushing in bone ends during palpation. Note any crepitation, depressions, deformities, or protrusions. Also note any tenderness to the head or scalp. Look at your gloved hands for evidence of blood when palpating. This is useful in patients with dark hair or at night when blood is difficult to see.

**Ears.** Inspect the ears for trauma to the external auditory canal. Look for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling. Move into a position to allow you to look inside the ear with a penlight for blood or other fluid (EMT Skills 13-3B). A clear fluid flowing from the ear is most likely cerebrospinal fluid (CSF), a clear fluid that surrounds and cushions the brain and the spinal cord. Leakage of CSF usually indicates a skull fracture. If bleeding is occurring from the ear, place a loose dressing over the ear to catch the blood. Do not pack the ears or restrict the bleeding.

Look behind the ears for discoloration over the bony prominence known as the mastoid process (EMT Skills 13-3C). Ecchymosis (black-and-blue discoloration) to the mastoid area is known as the Battle sign. This is a late sign of possible skull or head injury that may not appear until hours after the injury.

**ASSESSMENT TIPS**

A “halo test” has frequently been taught to be performed on blood and fluid leaking from the ears, nose, or mouth to determine if it contains cerebrospinal fluid. It was done by dropping blood onto a piece of cotton, such as a gauze pad, a pillowcase, or a sheet. If a yellow circle or “halo” formed around the blood, it was thought to be CSF. Research has found, however, that nasal secretions, saline, and other substances when mixed with blood will create the same effect. Therefore, this test is not reliable for identifying CSF leakage.

**PATHOPHYSIOLOGY PEARLS**

If time permits and you want to test to see if a clear fluid leaking from the ears, nose, or mouth is cerebrospinal fluid, place a drop of the clear fluid on a glucose test strip and test it in the glucometer. CSF contains sugar, whereas nasal secretions and other fluids do not. The sugar level in CSF is much lower than that found in blood. If the fluid is mixed with blood, this will not work since the blood itself contains sugar.

Do not delay transport to perform this test.

**Face.** Inspect the entire facial region to include the eyes, nose, and mouth. Look for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling. Palpate for deformity, swelling, and tenderness (EMT Skills 13-3D). Injuries to the face are typically dramatic and potentially life threatening. Bleeding or displacement of bone or tissue into the airway may cause an obstruction. Clear the airway with suction and insert an oropharyngeal airway if necessary and appropriate. Avoid the use of a nasopharyngeal airway. Palpate the facial bones for deformity, instability, and crepitation. If you note any trauma, continue to closely monitor the airway for bleeding and excessive swelling. Inspect and palpate the maxilla (upper jawbone) and mandible (lower jawbone) for any deformity or instability. The patient should be able to move the mandible without excessive pain. If the patient is unable to close his mouth, or if the teeth do not align well, the mandible is likely to be fractured or dislocated. With an injury to the maxilla or mandible, your major concern is maintaining a patent airway.

Inspect the face for singed or burnt eyebrows, nasal hair, beard, or hairline. Burns to the face should make you suspicious that the patient may be suffering from an upper airway burn. Upper airway burns frequently result in severe swelling and airway closure at the level of the larynx. If stridor (high-pitched sounds on inspiration) is noted, consider positive pressure ventilation with supplemental oxygen, immediate transport, and advanced life support intervention for advanced airway management.

In the medical patient, have the patient make a big smile and show his teeth while doing so to check for facial asymmetry (Figure 13-16). If the facial muscles are paralyzed you will note a droop to one side of the face. It is likely that you will miss the asymmetry if you examine the face without having him exaggerate a smile.

**Eyes.** Inspect for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling. Look especially for lacerations or trauma to the eyelids and eyeballs. Do not attempt to remove foreign bodies embedded in the eye. If the patient has burns, lacerations, or any other injuries to the eyelids, assume that the eye is also damaged. Do not force the eyelid open. Do not apply any pressure to the eye.

If the patient is unresponsive and is wearing hard contact lenses that are not properly positioned over the pupil, remove the lenses. Place them in a container with a small amount of saline, marking the container for the left and right contact. Be sure to transport the lenses with the patient. If the patient has a chemical burn to the eye, remove the contact lens to allow for adequate flushing. If the contact lens is left in place.

![Figure 13-16](image) Have the patient grin to check facial symmetry.
during flushing, the chemical trapped under the lens will continue to burn the eye.

Check for pupillary response (EMT Skills 13-3E). In a dark environment, shine a light in the eye of the patient. In a bright environment, shade the eye with your hand. Both pupils should react simultaneously and equally to light being shined in either eye. This is referred to as a consensual reflex. While shining a light into one eye, watch the pupillary reaction of the other eye. Then shine the light a second time in the first eye and watch the pupillary reaction of that eye. Thus, the light is shined in each eye twice, first to check the response of the opposite pupil to the light, and then to check the reaction of the pupil in the eye to which the light is applied. Observe whether pupil response is brisk or sluggish. Under normal conditions, the pupils should respond briskly. Poor perfusion to the brain, high levels of carbon dioxide, or brain injuries may cause the pupils to respond sluggishly.

Note the size of the pupils. Unequal pupils usually indicate a head injury or stroke. A pupil that is large in size and not responding to light is referred to as being fixed and dilated. In cardiac arrest or severe injury to the brain, both pupils may be fixed and dilated. Pupils that are pinpoint, or extremely constricted, and unresponsive usually indicate an injury to the brain stem or a patient under the influence of a narcotic substance. Also assess pupil shape. A teardrop-shaped pupil may indicate severe trauma.

A small portion of the population normally have unequal pupils. However, there is usually 1 mm or less difference, and their pupils remain reactive to light. It is extremely important to consider the patient’s level of responsiveness when determining the seriousness of the pupillary size. If the patient has unequal pupils but is completely alert and oriented, consider direct trauma to the eye, a localized nerve injury, or that the patient has used eye drops in front of the patient and have him follow it up, or by having him read your name tag. Hold your finger in front of the patient and follow it up, down, left, right, and in a circular pattern (EMT Skills 13-3F). This checks the extraocular muscle movements. The eyes should move together (conjugate movement) and smoothly. Jerky eye movements (nystagmus) usually result from drugs or central nervous system effects. A single eye that is fixed (fixed gaze) usually indicates a cranial nerve palsy. When the eyes do not move together (dysconjugate gaze) it usually indicates injury to the orbit, ocular muscles, or nerves, or intoxication (Figure 13-17). Note the size of the pupils. Unequal pupils usually indicate a head injury or stroke. A pupil that is large in size and not responding to light is referred to as being fixed and dilated. In cardiac arrest or severe injury to the brain, both pupils may be fixed and dilated. Pupils that are pinpoint, or extremely constricted, and unresponsive usually indicate an injury to the brain stem or a patient under the influence of a narcotic substance. Also assess pupil shape. A teardrop-shaped pupil may indicate severe trauma.

A small portion of the population normally have unequal pupils. However, there is usually 1 mm or less difference, and their pupils remain reactive to light. It is extremely important to consider the patient’s level of responsiveness when determining the seriousness of the pupillary size. If the patient has unequal pupils but is completely alert and oriented, consider direct trauma to the eye, a localized nerve injury, or that the patient has used eye drops in front of the patient and have him follow it up, or by having him read your name tag. Hold your finger in front of the patient and follow it up, down, left, right, and in a circular pattern (EMT Skills 13-3F). This checks the extraocular muscle movements. The eyes should move together (conjugate movement) and smoothly. Jerky eye movements (nystagmus) usually result from drugs or central nervous system effects. A single eye that is fixed (fixed gaze) usually indicates a cranial nerve palsy. When the eyes do not move together (dysconjugate gaze) it usually indicates injury to the orbit, ocular muscles, or nerves, or intoxication (Figure 13-17).

Check visual acuity (clarity of vision) by having the patient tell you how many fingers you are holding up or by having him read your name tag. Hold your finger in front of the patient and have him follow it up, down, left, right, and in a circular pattern (EMT Skills 13-3F). This checks the extraocular muscle movements. The eyes should move together (conjugate movement) and smoothly. Jerky eye movements (nystagmus) usually result from drugs or central nervous system effects. A single eye that is fixed (fixed gaze) usually indicates a cranial nerve palsy. When the eyes do not move together (dysconjugate gaze) it usually indicates injury to the orbit, ocular muscles, or nerves, or intoxication (Figure 13-17).

Inspect the white portion of the eye, termed the sclera, for redness or a yellow color. Yellow sclerae, known as icterus, is an indication of possible liver damage or failure. Pull the bottom part of the eye down and check the conjunctiva (EMT Skills 13-3G). Poor perfusion, as in shock, causes the conjunctiva to appear pale. Extremely red conjunctivae with reddened sclerae is typically caused by eye irritation.

Blood in the anterior eye is a sign that the eye or the head has received a forceful blow. Inspect the eye by shining a light from the side to detect a reddish discoloration over the iris (the colored portion around the pupil). This blood will typically form a straight fluid line across the cornea.

Nose. Inspect the nose for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling (EMT Skills 13-3H). Look for fluid or blood drainage, nasal flaring, and singed nasal hair. Bleeding from the anterior nose is usually easily controlled by pinching the nostrils together. However, some patients, especially the elderly with a history of high blood pressure, experience severe posterior nosebleeds in which the bleeding is difficult to control. Many times, the patient swallows large amounts of blood, becomes nauseated, and vomits. The vomitus contains blood and may be incorrectly assessed as internal bleeding in the stomach. The patient could lose a large volume of blood from the nosebleed.

Leakage of cerebrospinal fluid indicates a skull fracture, which may have an associated brain injury. Singed nasal hair should increase your suspicion that the patient has been involved in a fire and possibly has an upper airway burn.

Nasal flaring, which is identified by the nares (nostrils) opening wide during inspiration, is a sign of respiratory distress. Reassess the patient closely for other evidence of airway or breathing problems.

Palpate the nose for deformity, swelling, or instability. Your major concern with an injury to the nose is possible bleeding into the airway. Be prepared to suction the airway.

Mouth. Open the mouth and inspect for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling (EMT Skills 13-3I). Look for loose or missing teeth, loose or missing dentures, and discoloration of the mucosa (lining). Loose dentures should be removed in unresponsive patients so they do not fall back into the throat and become an airway obstruction. Remove any...
objects by suction or, if too large to suction, with your fingers. Inspect the tongue for lacerations and swelling, a possible sign that the patient has had a seizure (biting the tongue is common during seizures). Look for discoloration. Cyanosis (bluish color) of the mucosa indicates inadequate oxygenation. A pale tongue may indicate poor perfusion and shock. Any burns or extremely white areas may be caused by ingestion of a chemical poison.

Smell for any unusual odors. An alcoholic beverage odor may make you suspect alcohol intoxication as a reason for an altered mental status. It is always necessary to be suspicious that the patient’s condition is from some cause other than alcohol. Look for other evidence of trauma or medical illness. A fruity odor on the breath may indicate a diabetic patient with an abnormally high blood sugar level. Smell for other unusual odors like rubbing alcohol, cologne, cleaners, and solvents. A desparate alcoholic may drink cologne or cough syrup because of the alcohol content. Children may accidentally ingest cleaners or solvents. Antifreeze may be ingested by teenagers as a means to get drunk, which can be lethal.

Look for black sputum and burns inside the mouth if the patient was involved in a fire. Suspect upper airway burns and be prepared to aggressively manage the airway and breathing if burning to the mouth or face is noted.

The mouth may provide some signs as to the oxygenation, breathing, or perfusion status. However, your chief concern is to ensure that the mouth is clear of potential airway obstructions.

Assess the Neck

Inspect the neck much more closely than you did during the rapid assessment (EMT Skills 13-3f). Look for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling. Large lacerations of the neck must be covered with an occlusive dressing to prevent air being sucked into a large vein, causing an air embolus. With any trauma to the neck, you should suspect possible cervical spinal injury and provide in-line spinal stabilization, if it has not already been applied. If a cervical spinal immobilization collar is in place, you typically will not remove it to inspect or palpate the neck. Most devices are manufactured with a large hole on the anterior surface to permit reassessment of the neck for jugular vein distention (JVD), blood collecting under the skin, or tracheal deviation.

The neck may appear large or swollen. This may be due to blood collection in or around the tissues or air trapped under the skin. Because of the large vessels, bleeding in the neck could be severe. A hematoma (collection of blood) could compress the airway or trachea and cause obstruction. Air trapped under the skin may be better palpated than seen. If you palpate an unusual sensation of air under the skin, and feel or hear crepitation (cracking), it is a sign of subcutaneous emphysema. Subcutaneous emphysema (which means, simply, air under the skin) is a sign of trauma to the airway, respiratory tract, lung, or esophagus. You should closely reassess the chest for evidence of chest injury and closely monitor the breathing status.

Reassess the jugular veins for distention. The jugular veins slightly distend normally in the supine patient with a normal blood volume. If possible, the jugular veins should be assessed with the patient sitting at a 45° angle. If two-thirds of the jugular vein is filled or engorged from the base of the neck up toward the angle of the jaw, then JVD is present. Do not have the trauma patient with suspected spinal injuries sit up to check the neck veins. JVD is a sign of a possible tension pneumothorax (air trapped in the chest cavity as a result of chest or lung injury), pericardial tamponade (blood filling the sac around the heart), or congestive heart failure. It is vital to reassess the effectiveness of the breathing status, pulses, perfusion, and blood pressure if JVD is noted.

Check the trachea to ensure it is midline. A shifted or deviated trachea is a late sign of tension pneumothorax. It may be easier to palpate the location of the trachea than to see it. Start at the suprasternal notch (the indentation where the right and left clavicle come together at the top of the sternum) and palpate with your thumb and index finger to feel the position of the trachea. It should be midline all the way up to the larynx.

Since a tension pneumothorax is a life-threatening condition, whenever tracheal deviation is noted you must immediately reassess the breathing and perfusion status. If the trachea tugs or moves to one side during inhalation, there may be an airway obstruction in the bronchi. Reassess for adequate breathing.

Another sign to look for is excessive neck muscle use. These muscles become very prominent when a patient is having difficulty with inspiration. Check for other signs of respiratory distress and inadequate breathing and provide positive pressure ventilation with supplemental oxygen, if necessary.

If a cervical spinal immobilization collar was applied, the neck would have been quickly palpated for any deformities during the rapid assessment. If a collar is not in place, palpate the anterior neck and posterior neck for deformities or spasms.

Assess the Chest

In the trauma patient, if not already done, expose the chest completely. Inspect the chest (EMT Skills 13-3k) for evidence of trauma including open wounds, deformities, contusions, abrasions, burns, lacerations, or swelling. If an open wound is found, immediately occlude it with a gloved hand and apply a nonporous or an occlusive dressing taped on three sides or a commercial occlusive device. Watch for retractions (the muscles between the ribs pulling inward during inspiration), a sign of respiratory distress. Retractions are seen more often in infants and children than in adults.

Determine if the chest is rising and falling symmetrically (evenly on both sides) or if one side of the chest
appears to remain elevated during exhalation. Asymmetrical (uneven) chest wall movement is a sign of a significant chest injury.

Look for any segments of the chest that are moving inward during inspiration and outward during exhalation, opposite to the direction of the rest of the chest. This is referred to as paradoxical movement and is a sign of a flail segment. A flail segment is an immediately life-threatening injury that needs supplemental oxygen to maintain an SpO2 of 94% or greater and may require the application of continuous positive airway pressure (CPAP) or positive pressure ventilation, depending on the tidal volume and respiratory rate. Immediately following the blunt chest injury in which a flail segment has occurred, the muscles between the ribs will commonly spasm and keep the free rib section stabilized. Therefore, you may not see exaggerated movement of the flail segment and may not detect it during the earlier assessments. Later during the call, it may become apparent that the chest wall is moving paradoxically. Stabilization of the segment is necessary. Usually, palpation will more easily identify an unstable section. Closely palpate the sides of the chest since the most common site of a flail segment is to the lateral chest wall.

Feel the chest to confirm the findings of the inspection. Check for symmetry of respirations by placing each hand with the thumbs pointed inward toward the sternum (breastbone) over the right and left lower portion of the rib cage. Both hands should move an equal distance with each breath. Also palpate for any tenderness, instability, and crepitation (crackling or crunching sounds beneath the skin), signs of subcutaneous emphysema. Apply light pressure with both hands downward and inward, slightly compressing the rib cage. If there is any rib or muscular injury, the patient will complain of pain. If the patient is already complaining of chest pain from an injury, do not compress the chest. If you suspect possible rib fractures or chest wall injury, reassess the breathing status. Because of the pain, the patient may be purposely breathing extremely shallowly and rapidly, decreasing the adequacy of breathing.

**ASSESSMENT TIPS**

A patient with a simple rib fracture may breathe very shallowly and rapidly because of the pain associated with deeper breathing. By intentionally breathing shallowly, the patient is lowering his tidal volume and making his ventilation inadequate. This can lead to hypoxia in the patient with a rib fracture, particularly in the elderly and those with underlying lung disease. 

Palpate the sternum by pushing down gently with the ulnar edge of one or both hands. A pain response may indicate rib or sternum injury. Children’s rib cages are extremely pliable and flexible. Significant blunt or compression injury may not cause any fractures to occur; however, significant injury to the internal organs may be present. Look at the mechanism of injury and have a high index of suspicion if the mechanism of injury has been significant. Continuously monitor the patient for signs and symptoms of poor perfusion, respiratory distress, and shock.

Inspect and palpate the shoulder girdle (articulation of the clavicle and scapula), the clavicles (collarbones), and scapulae (shoulder blades) for deformity, crepitation, and tenderness. Palpate the clavicles with the pads of your fingers beginning at the sternum and moving toward the shoulder. Gently slide your hand under the back on each side to palpate each scapula. Cup your hand around the shoulder girdle and compress lightly. If the patient is not immobilized or secured to a backboard and does not have a suspected spinal injury, roll the patient or sit the patient forward to assess the posterior thorax, looking for signs of trauma. Prior to being immobilized to the backboard, the posterior thorax must be inspected and palpated for injury.

Inspect and palpate the entire anterior and lateral chest. Injuries could easily be missed if you do not look at the patient’s sides and in the axillary region (under the armpit).

**Auscultation.** Listen to the chest with your stethoscope to determine if the breath sounds are present or absent, equal or unequal, normal or abnormal (EMT Skills 13-3L). Place your stethoscope just below the second rib at the midclavicular line to listen to the apices of the lungs and just below the fourth rib at the midaxillary line for breath sounds in the bases. Compare the sounds of the lobes on both sides of the chest. Absent or diminished breath sounds are a sign of air, blood, or fluid in the chest cavity or obstruction of a bronchus. Typically only one side has diminished or absent breath sounds, indicating which lung is injured.

In the medical patient, breath sounds are important to auscultate if the patient is complaining of dyspnea (shortness of breath or difficult breathing), has hives and itching, or has a history of allergies, anaphylactic (severe allergic) reaction, asthma, emphysema, or chronic bronchitis.

Wheezes are prolonged, high-pitched sounds most often heard on exhalation. Wheezes indicate narrowing of the airways at the level of the bronchiole. Note whether the wheezing is diffuse (throughout the lung fields) or isolated to one section of the lung. Diffuse wheezing heard in all the lung fields is usually due to narrowing or spasm of the airways associated with asthma, anaphylaxis, emphysema, or chronic bronchitis. Isolated wheezing heard in only one area is a sign of localized lung infection, obstruction, or a foreign body.

Fluid collection in the lungs produces crackles, a sound sometimes called rales. A harsher rasping sound heard upon auscultation, called rhonchi, is from mucus in the larger airways within the lung.

Stridor, a high-pitched sound, is from partial obstruction of the upper airway at the level of the larynx. It is usually caused by a foreign body or swelling. Closely
monitor the airway and provide positive pressure ventilation with supplemental oxygen if inadequate breathing is found.

Coughing is a response to bronchial irritation. Smoke, chemicals, or other inhaled gases may cause the patient to cough. If you suspect the patient has inhaled a toxic substance such as smoke, place the patient on a nonrebreather mask at 15 lpm. If mucus is produced with the cough, which is referred to as a productive cough, note the color, consistency, amount, and odor. Mucus is normally white and clear. Yellow or green mucus is a sign of possible infection. Also note any blood-tinged sputum (substance produced by coughing). This may indicate lung injury, airway trauma, or a cardiac or pulmonary disease. Be sure to inspect inside the mouth for lacerations if blood is found in the sputum.

Assess the Abdomen

It is best to examine the abdomen with the patient lying flat (EMT Skills 13-3M). Notice the posture of the patient. A patient lying extremely still with his knees drawn up toward the chest and with breathing that is fast and shallow is most likely suffering from significant abdominal pain. Expose the abdomen and inspect all four anterior quadrants and the lateral aspects for obvious signs of injury such as deformities, contusions, abrasions, punctures, burns, or lacerations. Look for impaled objects or open wounds with protruding organs.

**Assessment Tips**

A patient with severe abdominal pain will often lie extremely still, draw his knees up toward the chest, and breathe fast and shallowly to reduce the movement of the diaphragm. The condition usually involves irritation of the peritoneum (lining of the abdomen). A patient who is complaining of pain but feels better if he is up and walking may be suffering from a bowel obstruction.

Look at the abdomen for signs of swelling or distention. The abdomen could be distended from air, fluid, or blood. If the abdomen appears to be distended, look for signs of poor perfusion and shock. A significant amount of blood must be lost in the abdomen before it distends. (Two liters of blood in the abdomen may distend the girth of the abdomen by only 1 inch.) Note any discoloration around the navel or in the flank areas. Bleeding in the abdomen may cause discoloration to these areas; however, this is a very late sign that takes several hours to develop.

The patient may have a colostomy or ileostomy. This is a surgical opening in the abdominal wall with a bag to hold excretions from the digestive tract. Leave the bag in place and be careful not to displace or cut it. Keep the bag covered from view to save the patient from possible embarrassment.

Ask if the patient is having any abdominal pain prior to palpating. Palpate all four quadrants of the abdomen separately using the pads of your fingers with one hand on top of the other. Roll the hands across the quadrant assessing for rigidity or stiffness, tenderness or pain, and distention. (A soft abdomen is normal.) If the patient is complaining of pain, have him point to the pain with one finger. If the patient can localize the pain in this manner, start your palpation at the point farthest away from the pain and move inward. Palpate the painful quadrant last. When palpating, listen to the patient’s response. In the unresponsive patient, watch the patient’s face and body movement for an indication of a painful response to palpation.

A pulsating mass in the abdomen may indicate that the abdominal aorta is weakened and bulging. If noted, stop any further palpation, rapidly complete the remainder of the secondary assessment, and begin immediate transport to a medical facility.

The patient may reflexively guard his abdomen by tightening the muscles. Voluntary guarding (guarding the patient is able to control) is common when you begin to assess the abdomen. Attempt to distract the patient with conversation to stop the guarding. If the abdomen remains rigid, it is a sign of peritonitis (inflammation or irritation of the lining of the abdomen) from blood, gastric contents, bacteria, or other substances. Taking a deep breath usually produces pain, so the patient typically breathes shallowly and fast.

A better test to perform is the Markle test, also called the heel drop test. If the patient is able to stand, have him stand up and get up on the balls of his feet, then suddenly drop down onto his heels (Figures 13-18a and 13-18b). Don’t tell the patient what you are testing for. Watch the patient’s face for a grimace, or note if he complains of pain to the abdomen. If the medical patient has pain to the abdomen, this is a positive for rebound tenderness, an indication of peritonitis or other inflammation within the abdomen, such as appendicitis. Perform a heel jar test if the patient is supine or unable to stand when you are assessing the lower extremities. Make a fist and strike the bottom of the heel forcefully enough to jar the abdomen (Figure 13-19). Again, don’t tell the patient what you are testing for and watch his face for a grimace. If he complains of pain, ask where. If it is to the abdomen, this is positive for rebound tenderness and probable peritonitis or other intra-abdominal inflammation.

**Pathophysiology Pearls**

Acids and other chemicals leaking into the abdominal cavity will usually produce pain immediately on contact with the peritoneal lining. The pain is typically sharp, constant, and severe. By contrast, bacteria leaking from the large intestine may take several hours to produce pain.

Do not palpate over obvious injuries or areas of severe pain. Do not poke the abdomen. If an impaled
Expose the pelvic area and inspect for deformities, contusions, abrasions, punctures, burns, lacerations, or swelling. Do not palpate if there is obvious injury or the patient is complaining of pain to the pelvis. Note any loss of bladder control or priapism. Priapism is a persistent erection of the penis in a male patient that is a sign of a possible spinal cord injury. Bleeding from the urethra or perineal bruising or hematoma are all signs of a urethral injury.

If the patient has no pain in the pelvic region or is unresponsive, place each hand on the anterior lateral wings of the pelvis and gently compress inward and downward. Do not rock the pelvis or apply unnecessary pressure. Assess for instability, tenderness, and crepitation. Place the base of your hand on the symphysis pubis (pubic bone), located immediately above the genitalia, and apply gentle pressure backward, checking for tenderness, crepitation, and instability.

**ASSESSMENT TIPS**

If the scrotum is swollen and red in a male patient with trauma to the pelvis, suspect a possible pelvic fracture with internal bleeding.

If serious trauma to the area of the genitalia is suspected—for example, penetrating trauma or major bleeding—expose and inspect the area. The male genitalia are relatively vascular (having many blood vessels); therefore, injury could result in significant blood loss. The female genitalia are most susceptible to penetrating trauma. Control bleeding to the external genitalia with direct pressure. If the female patient complains of vaginal bleeding, assess for signs and symptoms of shock.
To assess the amount of bleeding, ask the patient how many tampons or sanitary pads she has used since the onset of bleeding.

Respect the patient’s feelings of modesty or embarrassment. Explain what you are doing and why and protect the patient’s dignity and privacy by shielding the patient from the view of others during examination.

**Assess the Lower Extremities**

If any injury is suspected, cut the clothing away from the patient. Inspect the lower extremities, one at a time, from the hip to the toes (EMT Skills 13-3O). Look for deformities (e.g., angulation), contusions, abrasions, punctures, burns, lacerations, or swelling. Watch for abnormal positioning. Injuries to the hip or femur may cause the leg to shorten or rotate inward or outward.

In the medical patient, look for excessive swelling around the ankles (peripheral edema). This may be an indication of possible cardiac failure, especially to the right ventricle.

Palpate the extremity by placing a hand on each side of the leg with the thumbs anteriorly and touching, if possible, and the little fingers to the posterior. Begin at the level of the groin and palpate down to the feet. The hands should never lose contact with the leg. Feel for any deformities, angulation, crepitation, or depressions. Determine if the patient feels pain, tenderness, numbness, or tingling. In the medical patient, check for pain in the calf during dorsiflexion (pull his foot back and point his toes toward his head; Figure 13-20a ■) and plantar flexion (push his foot downward and point his toes away from the head). Also, palpate the calf for tenderness, swelling, or redness (Figure 13-20b ■). This may be an indication of a deep vein thrombosis and is a significant sign in a patient complaining of shortness of breath or fainting.

If an injury is suspected, remove the shoes or boots. It may be necessary to cut the laces to avoid any unnecessary manipulation of the foot or leg during removal.

If injury to the ankle or foot is suspected, cut the sock away. Ski boots should not be removed unless you are specially trained to do so.

Assess the distal pulses, motor function, and sensation. Loss of these functions is a sign of possible brain, spinal cord, or extremity injury.

**Pulses.** Assess the dorsalis pedis pulse on the top surface of the foot or the posterior tibial pulse located behind the medial malleolus (inner ankle bone) (EMT Skills 13-3P). Compare the equality of the pulses in the two lower extremities. While feeling the pulse, check the skin color, temperature, and condition. If the pulse is absent and the skin is pale or cyanotic and cool, expect a possible blocked artery in that lower extremity. A blocked vein causes the extremity to become flushed, warm, swollen, and painful. Pedal and tibial pulses are frequently absent in patients suffering from severe blood loss and shock.

**Motor Function.** Have the patient move his toes. Check for equality of strength in the lower extremities by placing your hands on the soles of both feet and having the patient push down against your hands (EMT Skills 13-3Q). Then place your hands on the dorsal surface of the feet and have the patient pull up against your hands. Note any inequality in strength. Do not check equality of strength if any obvious bone or joint injury is found in the lower extremity. Any unnecessary movement should be avoided. Unequal strength may be a sign of head, spinal, or extremity injury.

**ASSESSMENT TIPS**

If the foot or ankle is injured, you can still check motor function in the distal extremity by having the patient push against your finger and pull back against your finger with his great (big) toe. This should give you the same results as if the foot were tested.

Paralysis, in which the patient is unable to move the extremity, may result from head or spinal injury or a
stroke. Spinal injuries usually result in paraplegia (paralysis involving both legs only) or quadriplegia (paralysis involving both arms and both legs). A stroke or head injury commonly produces hemiplegia (paralysis of an arm and leg on one side of the body). A special exam for stroke will be discussed in Chapter 18, “Altered Mental Status, Stroke, and Headache.”

**Sensation.** Begin by lightly touching the toe on one foot and asking the patient to identify which toe you are touching (EMT Skills 13-3R). Then pinch the foot to elicit a pain response. Repeat the same procedure for the opposite foot. It is important to test both light touch and pain, since each stimulus is carried by a different spinal cord nerve tract. Record if the patient responds appropriately to both light touch and painful stimulus. Make sure the patient is unable to see which foot you are touching or pinching. The patient may provide the right response because he is able to see which toe you are touching instead of feeling it.

In the unresponsive patient, pinch the extremity while looking at the patient’s facial expression. A facial grimace usually indicates that the patient feels the pain. Also note any movement of the extremity, especially if it is withdrawal away from the source of pain. Clearly document the response to pain in your prehospital care report.

**Assess the Upper Extremities**

Inspect the upper extremities from the shoulder to the fingertips (EMT Skills 13-3S). Look for deformities (e.g., angulation), contusions, abrasions, punctures, burns, lacerations, or swelling.

Palpate the entire extremity by placing a hand on each side of the arm with the thumbs touching on the anterior surface. Start at the most proximal portion of the arm and move down to the fingertips. Feel for any deformity, crepitation, or swelling. Note any pain or tenderness the patient experiences. In the unresponsive patient, watch the patient’s face for grimacing and movement of the extremity that may indicate a response to pain. In the unresponsive patient, pinch the hand in an attempt to elicit a response. Watch the face for a grimace and movement of the extremity that may indicate a response to the pain. Repeat the process for the other hand. Clearly document the type of response and the type of painful stimulus in your prehospital care report.

**Assessment Tips**

On one side of the body, a patient may be able to move and feel light touch but can feel no pain. On the opposite side, he may be able to feel pain but is unable to feel light touch, or perhaps he can’t move on that side. These findings are consistent with a spinal cord injury that is incomplete, where some nerve tracts are intact and others are not.

**Assess the Posterior Body**

If the patient is not already secured to the backboard, roll the supine patient onto his side. If a spinal injury is suspected, manual in-line spinal stabilization must be maintained at all times until the patient is completely immobilized to the backboard. Inspect the posterior thorax, lumbar area, buttocks, and lower extremities for any deformities, contusions, abrasions, punctures, burns, lacerations, or swelling.

Palpate the posterior body for deformities and tenderness. If pain or tenderness is noted around any of the vertebrae, note the location and do not palpate the area. Palpating may cause further damage. If no pain is
noted, lightly palpate along the vertebrae for deformities or tenderness. Muscle spasm, tenderness, deformity, or pain to or around the vertebrae is a sign of vertebral injury. Be extremely cautious in handling the patient. Ensure proper in-line spinal stabilization and avoid any excessive or unnecessary movements.

**PATHOPHYSIOLOGY PEARLS**

While assessing the patient’s back, you may note muscle spasms along the vertebral column. These spasms may occur as a protective reflex to keep the injured or fractured vertebrae stable and in line following an injury.

If the patient is already immobilized to the backboard, do not roll him to assess the posterior body. Simply place your hand at the flank area and slide it as far under the patient as possible. Check for any obvious deformity or pain.

**Performing the Secondary Assessment: A Body Systems Approach**

An anatomical head-to-toe approach, as described in the prior sections, provides a systematic method in performing the secondary assessment. This systematic approach allows the EMT to perform the assessment in an organized manner, even when there is a great deal of distraction at the scene. Not performing the systematic head-to-toe approach leaves you vulnerable to missing injuries or signs of conditions that could be life threatening. Thus it is highly recommended you practice this type of approach throughout your career as an EMT.

Once an injury or condition has been identified, however, it is important not to focus on just that one particular anatomical region but rather to consider all other body systems that might also be affected. As an example, if the patient has a penetrating wound to the chest, it may have caused damage to the respiratory system and cardiovascular system which could lead to poor perfusion and cellular hypoxia. In this case, you must assess the respiratory, cardiovascular, and neurological systems to determine the extent of the injury. It is important to link the body systems together to establish the severity of the condition. In this case, you would perform a rapid secondary assessment from head to toe for two reasons: (1) to identify and manage additional penetrating or other life-threatening injuries, and (2) to determine the severity of the penetrating injury to the chest on perfusion and oxygenation.

The following is an example of the linkage of body system findings during the secondary assessment of the penetrating-chest-injury patient. The complete head-to-toe exam will be performed. Additionally, however, the body systems approach will help you to link findings from the complete head-to-toe exam that will provide information about the extent of the specific injury and its effects on other body systems. Linked findings from the head-to-toe exam of the penetrating-chest-trauma patient might include the following:

- Pupils that are dilated and sluggish may indicate hypoxia.
- Conjunctiva that is cyanotic may indicate hypoxia, and pale may indicate hemorrhage.
- Cyanotic oral mucosa indicates possible hypoxia.
- Distended jugular veins indicate possible backup of venous blood caused by impedance on the cardiac output from a tension pneumothorax or pericardial tamponade, leading to poor perfusion.
- Subcutaneous emphysema indicates a possible air leak from an injury to the lung or respiratory structure, which may lead to poor gas exchange and hypoxia.
- An open wound to the chest could interfere with lung expansion, leading to poor gas exchange and hypoxia.
- Decreased or absent breath sounds indicate a partially or completely collapsed lung that would cause a ventilation disturbance, poor gas exchange, and hypoxia.
- Extremities that are pale, cool, and clammy, with absent or weak peripheral pulses indicate vasoconstriction likely associated with blood loss leading to poor perfusion. Pale, cool skin and cyanosis indicate hypoxia.
- Decreased mental status indicates poor cerebral perfusion and cerebral hypoxia.

The major body systems assessment includes the respiratory (pulmonary), cardiovascular, neurological, and musculoskeletal systems. The body systems approach is integrated into the head-to-toe anatomical assessment. While conducting the head-to-toe exam, you must identify the findings that are related to the body systems and make the links. Body systems assessment should include, but not be limited to, the following:

**Respiratory (Pulmonary) System**

- Chest shape and symmetry
- Accessory muscle use (retractions)
- Auscultation (normal and abnormal breath sounds)

**Cardiovascular System**

- Peripheral and central pulse (rate, rhythm, strength, location)
- Blood pressure (systolic, diastolic, pulse pressure)

**Neurological System**

- Mental status (AVPU, orientation)
- Posture and motor activity (appropriateness of posture and movement, arm drift) (Review Figure 13-21.)
- Facial expression (anxiety, depression, anger, fear, sadness, pain, facial asymmetry or droop) (Review Figure 13-16.)
- Speech and language (slurred, garbled, aphasia)
- Mood (nature, intensity, suicidal ideation)
• Thoughts and perceptions
• Thought process (logic, organization)
• Thought content (unusual, unpleasant)
• Perceptions (unusual, auditory hallucinations, visual hallucinations)
• Memory and attention (orientation to person, place, time, purpose)

Musculoskeletal System
• Pelvic region (symmetry, tenderness)
• Lower extremities (symmetry, superficial findings, range of motion, sensory, motor function)
• Upper extremities (symmetry, superficial findings, range of motion, sensory, motor function, arm drift)
• Peripheral vascular system (tenderness, temperature, distal pulses)
• Perfusion (distal pulses, skin color, temperature, condition)
• Posterior body (symmetry, contour, superficial findings, flank tenderness, spinal column tenderness)

Assess Baseline Vital Signs
The assessment of vital signs will occur at different times depending on if you are dealing with a trauma or medical patient, if the patient is responsive or unresponsive, and if the patient is stable or unstable. Remember, however, that if you have enough assistance and can be sure that in-line stabilization is being maintained by a trained person, these steps may overlap. For example, one EMT may be able to get vital sign measurements while the other is conducting the physical exam, or vital signs and history may be taken at the same time.

The methods for assessing the vital signs were discussed in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” The following vital signs must be assessed during the secondary assessment and reassessed throughout the entire call:
• Breathing (rate and tidal volume)
• Pulse (location, rate, strength, regularity)
• Skin (temperature, color, condition)
• Capillary refill

• Blood pressure (both systolic and diastolic)
• Pupils (equality, size, rate of reactivity)
• SpO2

The vital signs with specific findings will be discussed further in the trauma assessment and medical assessment sections.

Obtain a History
The history was covered in detail in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” For a systematic approach, the EMT commonly uses the SAMPLE and OPQRST mnemonics in the history-taking process. You can use whatever approach or technique works for you as long as you collect all of the necessary information. The mnemonics have a tendency to keep the EMT from doing a shotgun approach to history taking and allow him to collect all of the necessary information.

Components of the SAMPLE history are:
• Signs and Symptoms
• Allergies
• Medications
• Past medical history
• Last oral intake
• Events prior to the incident

The OPQRST mnemonic is used to further evaluate the chief complaint and other complaints of the patient. As an example, if a patient complains of chest discomfort, shortness of breath, and nausea, the OPQRST mnemonic (onset, provocation/palliation, quality, radiation, severity, and time of the complaint) will be used to further investigate each of the complaints.

The history is conducted at different times in the secondary assessment depending on whether the patient is categorized as trauma or medical, responsive or unresponsive, and stable or unstable. The history is a much more important component of the secondary assessment of the medical patient than it is for the trauma patient. This will be discussed further in the section on assessment of the medical patient later in the chapter.
For the patient who has an injury or injuries rather than a medical condition, perform the secondary assessment for a trauma patient, which is generally performed in the following sequence:

1. Physical exam
2. Baseline vital signs
3. History

As mentioned earlier, you can often reduce the time before transport by performing some of these steps simultaneously. For example, while an Emergency Medical Responder maintains in-line stabilization, your partner might be taking vital signs and a history while you conduct the physical exam. Over a period of time, you and your partner can develop ways of accomplishing several things at the same time.

One of two kinds of physical exam can be chosen for a trauma patient: a **rapid secondary assessment** (a rapid head-to-toe exam) or a **modified secondary assessment** (an exam focused on a specific injury site), which will be described on the following pages. Your first decision during the focused history and physical exam will be which kind of exam is most appropriate for this patient:

- **A rapid secondary assessment** followed by prompt transport, or on-scene emergency care, or
- **A modified secondary assessment** followed by on-scene emergency care

The kind of physical exam you will conduct is based on the mechanism of injury—the force that caused the injury—and findings in your primary assessment. (Mechanism of injury was introduced in Chapter 12 and will be further discussed in Chapter 27.) You must determine whether the mechanism of injury is significant enough to have caused critical injury, if multiple injuries exist, if the patient has an altered mental status, or if any other critical finding identified in the primary assessment makes the patient unstable. If so, choose the rapid secondary assessment (the rapid head-to-toe exam) followed by prompt emergency care and transport. If the mechanism of injury is not significant enough to produce critical injuries, but you suspect the patient could be suffering from multiple or serious injuries anywhere on the body, or if the patient has an altered mental status, conduct a rapid secondary assessment as a basis for further on-scene emergency care. If the patient is suffering from an isolated injury that is not critical, the mechanism of injury is minor, there is no evidence of multiple injuries, and the patient is alert and oriented, conduct a modified secondary assessment of the injury site, followed by appropriate on-scene emergency care.

The following chart compares the two approaches.

### Secondary Assessment for a Trauma Patient Who Has …

#### A Significant Mechanism of Injury, Multiple Injuries, Altered Mental Status, or Critical Findings in Primary Assessment (or for Whom Unknown Injuries Are Suspected)

1. Rapid secondary assessment (head to toe)
2. Baseline vital signs
3. History

#### Isolated Injury with No Significant Mechanism of Injury, No Multiple Injuries, Alert and Oriented Mental Status, and No Critical Finding in Primary Assessment

1. Modified secondary assessment (focused on the injury site)
2. Baseline vital signs
3. History

### REEVALUATE THE MECHANISM OF INJURY

Your first step in the secondary assessment (Figure 13-22) is to re-evaluate the mechanism of injury. Remember, the mechanism of injury is directly related to the potential for critical injuries. The more significant or severe the mechanism of injury, the greater the chance that the patient is critically injured. You must ask yourself, “Was this mechanism of injury significant enough to cause critical or multiple injuries?”

The emergency care you provide is frequently based on the findings of the scene size-up and a high index of suspicion. Most often, spinal immobilization is performed based solely on your suspicion that the patient might have suffered an injury to the spinal column. You provide the necessary emergency care for a spinal injury even though you detect no signs or symptoms of such an injury.

When there is a significant mechanism of injury—as soon as you have completed the primary assessment and management of immediately life-threatening conditions—you should proceed with a rapid secondary assessment to identify any additional serious or potentially life-threatening injuries.

### Significant Mechanisms of Injury

Mechanisms of injury that have a high incidence of producing critical trauma are:

- Ejection (partial or complete) of the patient from a vehicle in an automobile crash
- A crash that causes death to a person in the same passenger compartment in which the patient is found
- A fall of greater than 20 feet
Rollover of the vehicle the patient was in (Figure 13-23a)
- A vehicle collision that has occurred at a high speed
- An intrusion of greater than 12 inches into the passenger compartment or greater than 18 inches at any site on the vehicle (Figure 13-23b)
- A pedestrian/bicyclist struck by a vehicle
- A motorcycle crash at greater than 20 mph with separation of rider from motorcycle
- Blunt or penetrating trauma that results in an altered mental status, from confusion to unresponsiveness

Significant mechanisms of injury include
(a) rollover of a vehicle a patient was in; (b) intrusion of greater than 12 inches into the passenger compartment or greater than 18 inches into any site on the vehicle.

**Special Considerations for Infants and Children**

For infants and children, significant mechanisms of injury would also include:
- A fall of greater than 10 feet or 2 to 3 times the height of the child
- A bicycle collision with a motor vehicle
- A pedestrian or occupant in a vehicle collision at a medium speed
- Any vehicle collision where the infant or child was unrestrained

All other mechanisms of injury that are significant for the adult are also significant in the infant and child.
Mechanism of injury is a vital component in the assessment of infants and children since they have a tendency to compensate for blood loss for a longer period of time compared to adults, then decompensate faster. (This phenomenon will be explained in Chapter 15, “Shock and Resuscitation,” and Chapter 38, “Pediatrics.”) Consequently, an infant or child may appear to be well even though injured as severely as an adult who displays all the signs of shock. When that infant or child does deteriorate, it will happen very rapidly and perhaps too late for emergency care to save the child’s life. So for the infant or child, even more than for an adult, you must rely on the mechanism of injury in your assessment. If there is a significant mechanism of injury, you must assume that the child is critically injured and in shock, even if the child looks all right, and provide treatment accordingly.

**ASSESSMENT TIPS**

If the patient—adult or child—has not suffered a significant mechanism of injury (MOI) but is exhibiting signs and symptoms of shock or a severe injury, assume the patient is injured and provide immediate emergency care based on the clinical findings and not the MOI.

---

**Rapid Secondary Assessment: Trauma Patient with Significant Mechanism of Injury, Altered Mental Status, Multiple Injuries, or Critical Finding (Unstable)**

If any of the significant mechanisms of injury listed earlier are encountered at the scene, if the patient has an altered mental status, if you are unsure of the extent of injury to the patient, if you cannot clearly identify the mechanism of injury, if multiple injuries exist or are suspected, or if critical findings were identified in the primary assessment, you should proceed with a rapid secondary assessment to quickly identify other life threats and prepare the patient for rapid transport.

The rapid secondary assessment is a head-to-toe physical exam that is swiftly conducted on a patient who has suffered or may have suffered severe injuries. If the patient is responsive, he can be questioned as to symptoms and history while the exam is in progress. This will aid in identifying injuries and related problems the patient may be suffering from, such as breathing difficulty. If the patient is unresponsive, the rapid secondary assessment alone can identify a majority of the injuries.

Prior to performing the rapid secondary assessment, make sure that spinal stabilization—established during the primary assessment—is continued. Consider requesting ALS backup, reconsider your transport decision, and reassess the patient’s mental status. These steps are described in further detail in the next sections.

**Continue Spinal Stabilization**

Maintain in-line spinal stabilization until the patient is completely immobilized to a backboard. While one EMT performs the rapid secondary assessment, another EMT or assistant should continue to hold the head and neck in a neutral in-line position until a cervical spinal immobilization collar is applied; the patient is placed on the backboard and strapped in place, and a head immobilization device is applied. Once manual spinal stabilization is established, it should never be released until immobilization is completed. Typically, complete immobilization of the patient will not be performed until the rapid assessment is completed.

**Consider an Advanced Life Support Request**

Some trauma patients may benefit from advanced life support at the scene or while en route to the hospital. Airway trauma, an occluded airway, or any indication that air from an injured lung is trapped in the chest cavity, causing the uninjured lung and the heart to be compressed (tension pneumothorax), may be reason to consider calling for advanced life support. These are life-threatening problems in which advanced airway maneuvers or chest decompression could be life saving. These decisions should not delay transport to an appropriate facility. Follow local protocols and consult medical direction.

**Reconsider the Transport Decision**

Normally, if a decision for immediate transport has not been reached at the end of the primary assessment, transport will take place after the rapid secondary assessment, assessment of baseline vital signs, gathering of the history, and completion of appropriate emergency care based on these assessments. Throughout the exam, however, keep in mind the possibility of immediate transport if evidence of critical injury or deterioration is discovered.

**Reassess Mental Status**

Any deterioration in the patient’s condition can have an adverse effect on functioning of the brain and a consequent deterioration in mental status. Therefore, continuous reassessment of the patient’s mental status is necessary to provide you with valuable information regarding the deterioration or improvement of the patient’s condition. This is often referred to as “trending.”
Common causes of decreased mental status in trauma patients are compromised airways, inadequate breathing, hypoxia, blood loss, poor perfusion, poor oxygenation, and brain injuries. These commonly result from:

- Bleeding or trauma to the face, mouth, or neck
- Head injuries
- Chest injuries
- Abdominal injuries
- Bone injuries associated with blood loss

### Critical Findings: Unstable Trauma Patient

<table>

</tr>
<tr>
<td>Emergency Care:</td>
<td>Establish an airway, begin positive pressure ventilation at 10–12/minute if respiratory rate or tidal volume is inadequate, and administer oxygen.</td>
</tr>
</tbody>
</table>

### ASSESSMENT TIPS

The mental status of a patient with a brain injury will continue to deteriorate or will not improve if it is already altered.

A patient who is already unresponsive upon your arrival at the scene should be considered seriously injured. If a responsive patient’s mental status shows signs of deteriorating, you should move rapidly through the assessment, looking for the potential cause of the unresponsiveness or deterioration of the mental status, and take steps to immediately correct the problem. To assess mental status, use the AVPU method (alert, responds to verbal stimulus, responds to painful stimulus, unresponsive) that was described in Part 2 of this chapter.

In an alert patient, assess the level of orientation. This is accomplished by asking the following questions about the time, place, and person/self:

- Do you know what year, month, and day it is?
- Can you tell me where you are right now?
- Who is this person with you?
- What is your full name?

Determine if the patient can provide you with the year, month, day, and approximate time of day. Orientation to place is assessed by asking the patient if he can identify where he is. If he is at home, he should be able to provide you with his address. If he is in an automobile crash, he should be able to tell you where he was coming from and where he is going. If he is at the mall or a store, he should be able to give the name of the mall or the store he is in. If another person is at the scene who is a friend or relative of the patient, have the patient identify him or her. If no other person is with the patient at the scene, it is somewhat difficult to assess for orientation to person. Finally, ask the patient his own full name.

If the patient correctly answers all of the questions, he is noted to be alert and oriented to time, place, and person/self. Commonly, this is documented as “alert and oriented × 3.”

Orientation to time is usually the first to be lost in a deteriorating mental status. As the patient continues to progressively deteriorate, he will lose orientation to place, then person, and finally to his own self. At this point, he would not be able to identify himself or anyone else at the scene.

If the patient is not alert, determine what type of stimulus is needed to arouse the patient. As described in Part 2 of this chapter, first attempt verbal stimulus. If the patient does not respond to verbal stimulus, attempt painful stimulus.

The patient may respond in the following ways to a verbal stimulus:

- Responds to verbal stimulus with inappropriate words
- Responds to verbal stimulus with comprehensible sounds, such as mumbling
- Responds with eye opening or obeying a command
- No response to verbal stimulus

The patient may respond to a painful stimulus with:

- Purposeful movements aimed at attempting to remove the stimulus, such as grabbing your hand or making a pushing-away gesture
- Nonpurposeful movements noted by flexion or extension posturing (back arched, arms pulled upward toward the chest or extended parallel to the body) that is not an attempt to remove the stimulus
- No response

Document precisely the alert patient’s orientation or the nonalert patient’s response to verbal or painful stimulus. Examples: “The patient is alert and oriented to person and self but not time or place,” or “The patient responds to painful stimulus with upward movement of the left arm only.” This information provides other emergency personnel with criteria to use later to determine if the patient’s mental status has improved or deteriorated. The Glasgow Coma Scale (GCS) (Tables 13-9 and 13-10) is used to rank the patient’s level of consciousness by assigning a numeric score from 3 to 15. This scoring tool is used in emergency medical services to identify trends of improvement or deterioration in the mental status of the patient. The GCS score is widely accepted, is reproducible, and can be reported and recorded as evidence of the mental status trending. A GCS score of 8 or less indicates a severe alteration in brain function. A GCS score of 13 or less is an indication for limited on-scene time (less than 10 minutes) and rapid transport.
If bystanders, relatives, or friends are present at the scene, it is important to determine from them if the patient suffered an altered mental status, lost orientation, or became unresponsive at any time prior to your arrival. If the patient is unresponsive, determine if the patient was responding and oriented at any time after the incident but prior to your arrival. Also note if the patient lost responsiveness, awoke for a period of time, and then became unresponsive again. Most of these are reliable indicators of possible head injury. Patients with these patterns of responsiveness and loss of responsiveness need very close monitoring.

Perform a Rapid Secondary Assessment

When performing the rapid secondary assessment, you will inspect and palpate the patient to identify signs and symptoms of potential injuries. Also, auscultation could reveal a collapsed lung and potential life-threatening chest injuries.

During the rapid secondary assessment of each major body area, inspect and palpate for evidence of trauma. Common signs of trauma include deformities, contusions, abrasions, punctures and penetrations, burns, tenderness, lacerations, and swelling (EMT Skills 13–4).

This is not an all-inclusive list; many other signs and symptoms should be assessed for as evidence of trauma:

- **Inspect (look) for** deformities, contusions (bruises), abrasions, punctures, penetrating wounds, burns, lacerations, swelling, unusual chest wall movements, angulated extremities, bleeding, discoloration, open wounds, and significant bleeding.

- **Palpate (feel) for** tenderness, deformities, swelling, masses, muscle spasms, skin temperature, and pulsations. When palpating for tenderness (pain on palpation) in the unresponsive patient, watch the patient’s face for grimacing. This provides a good indication that tenderness is present without the patient being able to tell you.

- **Auscultate (listen with a stethoscope) for** presence and equality of breath sounds.

- **Listen for** sucking sounds, gurgling, stridor (high-pitched sound of the upper airway), and crepitation (grating sound heard when broken bone ends rub against each other, or a crackling sound caused by air under the skin).

- **Use your sense of smell to** detect any unusual odors on the patient’s breath, body, or clothing, such as alcohol, feces, or urine.

As you conduct the rapid secondary assessment, talk calmly to the patient, even if he appears to be unresponsive. Don’t distress the patient by describing wounds and injuries, but rather indicate what areas you are going to assess. In the responsive patient and if the condition permits, ask any relevant questions about the area to be assessed prior to examining it. If you assess the area and then ask questions, the patient will suspect that you have found something wrong.

In the rapid secondary assessment, be most concerned with identifying potentially life-threatening injuries. If you find any injuries that are potentially life threatening, you must manage them immediately to avoid further deterioration of the patient. Each situation is different and will dictate how you proceed.

Be careful not to move the patient unnecessarily to avoid aggravating any neck or spinal injury that might exist. Do not manipulate the patient to attempt to remove clothing. If necessary, expose the areas to be examined by cutting the clothing off the patient. In patients with a significant mechanism of injury or for whom serious trauma is a possibility, it is important to completely expose the patient to look for additional injuries.

**Assessment Tips**

A distracting injury, such as an extremity fracture, may cause the patient to not complain of other, more significant or critical injuries, such as a knife wound to the chest. If a patient has a distracting injury, expose him completely to assess for other, more potentially life-threatening injuries that he may not be complaining of.

Suppose that you arrive on the scene of a shooting and find a patient with a gunshot wound to the left upper thigh. It appears the bullet fractured the femur. Because the femur fracture is so painful, the patient is only complaining of that injury. You focus in on the femur fracture and neglect to expose the patient to look for any other injuries. It is winter and the patient has a heavy coat on. It is nighttime, and the patient is wearing dark clothing. Therefore, it is difficult to see blood. The patient was shot with a .22 caliber gun, which is very small. En route to the hospital, the patient begins to complain of severe breathing difficulty. You finally become suspicious and expose the chest to find a gunshot wound of the anterior chest. You missed a life-threatening injury in this patient. If you had quickly exposed the chest during your assessment, you would have found the injury.

When exposing the patient, keep modesty and environmental conditions in mind. Do not completely expose the patient in front of a crowd or television camera. Cover the patient with a sheet to protect the modesty of any patient, male or female, young or old. Also, do not inadvertently induce hypothermia by exposing the patient to the cold. Consider moving into the ambulance before completely exposing the patient.

As described in the following sections, the rapid secondary assessment is performed in a systematic sequence to ensure that all major body areas are inspected and palpated (EMT Skills 13-5).

**Assess the Head**

When examining the head, it is necessary to quickly examine the skull, scalp, face, ears, pupils, nose, and mouth. *The exam is not detailed unless an injury is found or suspected in that particular area. A more detailed exam of each area can be conducted at a later time.* You are primarily concerned with identifying a possible head injury by examining the scalp, skull, pupils, and ears. Also, you must quickly reassess the nose and mouth for potential obstructions of the airway.

**Scalp and Skull.** Inspect the scalp and skull (EMT Skills 13-5A) for any obvious deformities, contusions, abrasions, punctures, burns, lacerations, swelling, depressions, protrusions, impaled objects, or bleeding. Palpate for any crepitation (grating sound or feeling resulting from fractured bone ends rubbing together), depressions, protrusions, swelling, bloody areas, instability, or lack of symmetry. Listen for any sounds the patient makes and look for flinching or grimacing that reveals any tenderness the patient experiences when you are palpating. If you discover burns or the patient’s hair is singed, suspect that the patient was involved in a fire and pay particular attention to the airway, breathing, and oxygenation status.

Palpate the scalp and skull by cupping your hands and moving from the frontal region to the back of the skull. Do not poke with your fingers, since you may
aggravate a depressed skull fracture by pushing the bony ends into the brain. Be careful not to move the head or neck when palpating in the patient with a suspected spine injury.

In a dark environment, it is difficult to see blood in the hair. Thus, when assessing the head, periodically look at your gloves for evidence of blood. Also, pay attention to areas that feel warm during the exam as this usually indicates leakage of blood or cerebrospinal fluid. Leakage of cerebrospinal fluid is evidence of a skull fracture.

Avoid unnecessary pressure to any areas of the skull that appear unstable, depressed, or deformed. Refrain from palpating the depressed or deformed area to avoid further injury. If an impaled object is found in the skull, stabilize it in place with bulky dressings. Do not remove or move the object. (Management of impaled objects will be discussed in detail in Chapter 28, “Bleeding and Soft Tissue Trauma,” and Chapter 33, “Eye, Face, and Neck Trauma.”) Abnormalities to the skull, especially with an altered mental status, are a clear indication of a critical head injury that requires prompt attention and transport.

A severe and detrimental condition that may occur in a head injury is called **brain herniation**. This occurs when a significant amount of swelling and/or bleeding to or around the brain creates excessive pressure within the skull and causes the brain to be compressed and pushed downward toward the brain stem at the base of the skull. Herniation results when a portion of the brain is pushed out, usually through the foramen magnum, the opening through which the spinal cord exits from the brain, or through the fibrous tentorium, which divides the upper and lower brain. Compressed brain tissue does not function properly. If the medulla in the brain stem is compressed, the respiratory center, cardiac center, and vasomotor center (which controls blood pressure) will not function. This will quickly lead to death.

Assess for signs of brain herniation and treat the patient aggressively. Signs of brain herniation include a severely altered mental status, abnormal posturing (flexion or extension), fixed pupils, or unequal pupils. If the patient has a suspected head injury and is displaying signs of herniation and is breathing inadequately, an airway must be established and the patient artificially ventilated. Hyperventilation may be considered; however, this emergency care is controversial and may not be recommended in your local protocol. Always follow your local protocol. Hyperventilation is achieved by positive pressure ventilation initiated and maintained at a rate of 20 ventilations per minute in the adult patient. If there are no signs of brain herniation but the patient is not breathing adequately, establish an airway and provide positive pressure ventilation at a rate of 10–12 ventilations per minute. If the patient is breathing adequately (i.e., both rate and tidal volume are adequate), administer supplemental oxygen. (Head injuries will be discussed in detail in Chapter 31, “Head Trauma.”)

### ASSESSMENT TIPS

**Bradycardia** (a slow heart rate) in a patient with a suspected head injury is a very serious sign of brain injury.

Even though prompt transport is key in treatment of the patient with a head injury, it is vital to continue with the exam to identify any other potential injuries that need immediate attention. For example, the patient could die from an open wound to the chest that you missed because of failure to continue with the exam.

If the patient is wearing a hairpiece or a wig, do not attempt to remove it. It may be held in place with permanent adhesive or tape or may be sewn into the scalp. Feel gently through the netting to assess for bleeding, swelling, or deformity. Do not reach under the wig.

**Face.** Inspect the face (EMT Skills 13-5B), looking for any evidence of trauma and bleeding that may be obstructing the airway. Look for deformities, contusions, abrasions, penetrating wounds, lacerations, swelling, or other evidence of trauma. Palpate for deformities, instability, and swelling.

Of particular concern is trauma to the midface region. This is a common injury from blunt forces being applied to the area between the lower lip and the bridge of the nose. A patient who strikes his face on the dashboard in an automobile crash commonly suffers trauma to the midface. Also, blows to the face from punches, kicks, baseball bats, or other objects will cause significant trauma.

If trauma to the face is found, carefully assess the airway for possible occlusion. Many times the bones of the face are pushed posteriorly into the airway, causing a blockage. Bleeding, which is common with injuries to the face, may occlude the airway or increase the risk of
aspiration of the blood (the patient breathing the blood into the lungs). Insertion of an oropharyngeal airway and constant suction may be necessary to maintain a patient airway. Do not use a nasopharyngeal airway when injuries to the midface are present. The airway may be improperly placed, with the risk of the airway entering the skull, because of a fracture to the nasal structures.

When inspecting the face, in addition to looking for burns to the skin, look for singed or burned nasal hair, eyebrows, and facial hair. This would indicate that the patient has potentially suffered an upper airway burn. Reassess the airway for stridor and adequate air movement. If stridor is present, begin positive pressure ventilation with supplemental oxygen.

Pupils. Assess the patient’s pupils by opening the eyes and shining a penlight into each eye, checking for equality of pupil size and reactivity. The pupils are normally equal in size and constrict briskly to light. Unequal pupils (Figure 13-25 ■) or pupils that do not respond to light (fixed pupils) usually indicate a severe head injury. Poor tissue perfusion and hypoxia (inadequate oxygen supply) will cause the pupils to respond sluggishly.

If a patient has unequal pupils but is alert and oriented, the unequal pupils are probably not from a head injury. You need to suspect a possible eye injury, effect of eye medications, or some other condition. Approximately 6 to 10 percent of the population normally have unequal pupils. This is termed anisocoria.

**ASSESSMENT TIPS**

You may meet more resistance when ventilating a patient with stridor because of the increase in resistance to airflow through the swollen larynx. If you feel resistance, however, make sure it is not from a poorly established airway.

**Ears.** Quickly look inside the ears with a flashlight. Inspect for leakage of blood, cerebrospinal fluid, or other fluid, which are signs of a possible head injury (Figure 13-24 ■).

**Nose.** Inspect the nose for evidence of bleeding and leakage of cerebrospinal fluid. Suction the nose clear of blood if it is draining posteriorly into the nasopharynx. Your major concern with the nose is bleeding into the airway, causing occlusion or possible aspiration. Check the nose for burned nasal hair or carbonaceous (charcoal black) discharge. This indicates likely inhalation of smoke and a possible upper airway burn.

**Mouth.** Your major concern when inspecting the inside of the mouth is to reassess the patency of the airway. Inspect for any bleeding, bone fragments, or dislodged teeth that may need to be suctioned or removed by finger sweeps. Also, inspect for swelling, lacerations to the tongue, and tissue damage that may cause possible obstruction.

When inspecting inside the mouth, look at the color of the mucous membranes. The mucous membranes are normally pink. Cyanotic membranes indicate hypoxia and pale membranes indicate poor tissue perfusion, possibly from long-term blood loss.
If the patient is being ventilated, quickly inspect the inside of the mouth in between ventilations. Never interrupt ventilation for more than 30 seconds.

Assess the Neck

Inspect the anterior neck (EMT Skills 13-5C) for deformities, contusions, abrasions, punctures, burns, lacerations, swelling, and any other evidence of trauma. A large collection of blood under the skin in the neck might actually occlude the airway by compressing the posterior portion of the trachea. Any large puncture wound or laceration to the neck must be immediately covered with an occlusive dressing (one that will not allow air through) and taped on all four sides. This is to prevent the possibility of air being sucked into a large vein and causing an air embolus. (Neck injuries will be discussed in detail in Chapter 33, "Eye, Face, and Neck Trauma.")

</tbody>
</table>

Inspect the neck for evidence of subcutaneous emphysema. Subcutaneous emphysema is air trapped under the lower layer of the skin. It appears as if the skin is bloated or inflated. Air leaking from the trachea, bronchus, bronchiole, lung, or esophagus will commonly collect in the neck. Thus, subcutaneous emphysema is a good indicator of a significant chest or neck injury. It may be easier to find subcutaneous emphysema when palpating. It feels like bubble package wrap. Crepitation (a crackling sound) when palpating is an indication of air trapped under the skin.

Look at the trachea to determine if it is midline. A trachea shifted to one side is a late indication of a significant amount of air trapped in the pleural space of the chest cavity, the result of a severe lung or chest injury. The trachea will deviate away from the injured side. This condition is a tension pneumothorax. Also, look for a pendulum motion of the trachea called tracheal tugging. This usually indicates an airway obstruction on the side the trachea moves toward.

Assess the jugular veins for distention (Figure 13-26). Normally, the jugular veins are slightly engorged in a patient who is lying supine. With the patient at a 45° angle, however, the neck veins should be flat. If the patient has neck veins that are flat in a supine position, it may indicate a decreased blood volume from bleeding. If the neck veins are engorged more than two-thirds the distance from the base of the neck to the angle of the jaw, they are considered to be distended. In trauma, JVD is a sign of a serious injury to the chest, lungs, or heart.

**PATHOPHYSIOLOGY PEARLS**

Veins in the neck drain downward toward the heart. A laceration to a large vein in the neck may cause air to be sucked into the vein as it is draining toward the heart. If the air bubble (embolus) is large enough, it will likely be caught up in the circulation in the lungs, blocking blood flow and causing hypoxia.

Inspect the neck for evidence of subcutaneous emphysema. Subcutaneous emphysema is air trapped under the lower layer of the skin. It appears as if the skin is bloated or inflated. Air leaking from the trachea, bronchus, bronchiole, lung, or esophagus will commonly collect in the neck. Thus, subcutaneous emphysema is a good indicator of a significant chest or neck injury. It may be easier to find subcutaneous emphysema when palpating. It feels like bubble package wrap. Crepitation (a crackling sound) when palpating is an indication of air trapped under the skin.

Look at the trachea to determine if it is midline. A trachea shifted to one side is a late indication of a significant amount of air trapped in the pleural space of the chest cavity, the result of a severe lung or chest injury. The trachea will deviate away from the injured side. This condition is a tension pneumothorax. Also, look for a pendulum motion of the trachea called tracheal tugging. This usually indicates an airway obstruction on the side the trachea moves toward.

Assess the jugular veins for distention (Figure 13-26). Normally, the jugular veins are slightly engorged in a patient who is lying supine. With the patient at a 45° angle, however, the neck veins should be flat. If the patient has neck veins that are flat in a supine position, it may indicate a decreased blood volume from bleeding. If the neck veins are engorged more than two-thirds the distance from the base of the neck to the angle of the jaw, they are considered to be distended. In trauma, JVD is a sign of a serious injury to the chest, lungs, or heart.

**FIGURE 13-26** Jugular vein distention. (© David Effron, MD)
The jugular veins drain downward into the superior vena cava and into the right side of the heart. If the right side of the heart is not able to off-load the blood effectively, if the heart is being compressed and not able to fill completely, or if the superior vena cava is kinked or compressed, the pressure and volume of blood inside the jugular vein will increase and produce the distended appearance.

**ASSESSMENT TIPS**

If the patient exhibits the signs and symptoms of shock or hypoperfusion and you find jugular vein distention on inspection of the neck, look for a cause of poor perfusion other than blood loss.

**ASSESSMENT TIPS**

If jugular vein distention is present, the veins in the hand will likely be engorged with blood and distended.

Inspect the posterior portion of the neck (EMT Skills 13-5D) for evidence of trauma. Look for deformity, contusions, and swelling. If in-line stabilization is being maintained, do not have it released to inspect or palpate. Inspection is difficult to accomplish with in-line stabilization. You may only be able to gently palpate the posterior cervical region for any deformities, tenderness, or muscle spasms. Do not move the head or neck to palpate. It is better to skip the inspection than to jeopardize the in-line stabilization and cause further injury.

Note any muscle spasms in the posterior cervical region. Muscle spasms occur in cervical injuries as a protective reflex, in an attempt to maintain support. Thus, a patient complaining of muscle spasms anywhere along the vertebral (spinal) column who has a mechanism of injury consistent with vertebral injury needs spinal immobilization.

Inspect the larynx for evidence of deformity and swelling. Injuries to the larynx from steering wheels, clothesline injuries, kicks, punches, and other blunt trauma could cause serious airway occlusion. With larynx injuries, the patient is typically hoarse or cannot speak, shows signs of respiratory distress, and may cough up blood. Oropharyngeal or nasopharyngeal airways are of no use in an isolated laryngeal injury because they do not reach to the depth of the injury. If the patient is unable to breathe adequately, you must provide positive pressure ventilation at a rate of 10–12/minute with supplemental oxygen. If the patient is able to breathe adequately, administer supplemental oxygen.

**ASSESSMENT TIPS**

A patient who is hoarse or cannot speak and who has evidence of trauma to the neck may have an injury to the larynx.

The patient may have a stoma, which is a surgical opening at the base of the throat. The stoma usually has a plastic or metal tube in the opening. The patient breathes through this opening. Therefore, make sure the tube is not occluded by blood, mucus, or other secretions.

**Apply a Cervical Spinal Immobilization Collar**

If the patient is suspected of having a possible spinal injury, a cervical spinal immobilization collar (CSIC) must be applied as soon as assessment of the neck is completed (EMT Skills 13-5E). The person who is maintaining manual in-line spinal stabilization continues to do so while the CSIC is sized and applied. It is very important not to move or manipulate the head or neck while applying the CSIC. At no time should in-line spinal stabilization be let go before, during, or after application of the CSIC. Even after the CSIC is properly applied, in-line spinal stabilization must be maintained until the patient is completely immobilized to a backboard with straps and a cervical spinal immobilization device. See Chapter 32, “Spinal Column and Spinal Cord Trauma,” for the proper techniques of measuring and applying the CSIC and providing immobilization.

If the cervical spinal immobilization collar has been applied prior to your arrival by Emergency Medical Responders or by additional EMTs during the primary assessment, do not remove the cervical collar to assess the neck. Inspect and palpate for evidence of trauma as best you can through the large opening in the front of the collar.

**Assess the Chest**

In order for the chest to be properly examined, it is necessary to expose it (EMT Skills 13-5F). Cut the clothing from the patient. Inspect the chest anteriorly, laterally, and in the axillary regions (armpits) for open wounds (Figure 13-27a ■). Any open wound to the chest must be immediately covered with your gloved hand. Then apply an occlusive dressing taped on three sides over the wound. The dressing will prevent air from entering the thorax (pleural space) and worsening the chest injury. The loose side will possibly allow air to escape during exhalation, relieving the possible buildup of air in the chest.

Inspect the chest for evidence of deformities, contusions, abrasions (Figure 13-27b ■), burns, lacerations, swelling, lack of symmetry, and any other evidence of trauma. Look for segments of the chest that are moving in a paradoxical movement. Paradoxical movement occurs when a section of the chest sinks inward upon inhalation while the rest of the chest is moving outward, and upon exhalation bulges outward while the rest of the chest is moving inward.

This type of motion may be seen when two or more adjacent ribs are fractured in two or more places. This is termed a flail segment. A flail segment interferes with the effectiveness of chest wall movement, altering the negative pressure in the chest and causing the alveoli to
collapse, thus reducing the adequacy of breathing and oxygenation. Since this is a life-threatening injury, you must immediately assess the adequacy of the ventilation and oxygenation. It is necessary to administer supplemental oxygen to maintain an SpO₂ of 94% or greater. If the patient has adequate breathing but is in respiratory distress, and meets the criteria for and has no contraindications for CPAP, consider application of CPAP. If the breathing is inadequate, begin positive pressure ventilation at 10 to 12 ventilations per minute and ensure that supplemental oxygen is applied to the ventilation device. Do not apply any type of stabilization or pressure that will impede the chest wall movement. If applied, this will lead to more alveolar collapse from poor lung expansion and a greater degree of hypoxia. A flail segment is usually accompanied by a severe contusion (bruise) to the lung, causing hypoxia.

**ASSESSMENT TIPS**

A flail segment may initially be stabilized by contraction of the muscles between the ribs (intercostal muscles). This will suppress paradoxical movement that would otherwise alert you to the presence of a flail segment. As the intercostal muscles fatigue, however, the stabilization is lost and the paradoxical movement becomes much more obvious. It is important to palpate for a flail segment early in your assessment, even though paradoxical movement may not yet be obvious.

**PATHOPHYSIOLOGY PEARLS**

A flail segment may interfere with the ability of the thorax to produce the pressure changes necessary to effectively move air in and out of the lungs. This can be easily overcome by the EMT who provides positive pressure ventilation so that the thorax no longer needs to generate pressure changes to draw in air.

Determine if the patient is in respiratory distress by inspecting the intercostal muscles (the muscles between the ribs) and the muscles above the suprasternal notch (the notch where the clavicles come together above the sternum). If the muscles are retracted inward during inhalation, it is likely that the patient is having a difficult time breathing. Look for flaring at the nostrils, use of the neck muscles, and excessive use of the abdominal muscles. If you suspect the patient is in respiratory failure, begin positive pressure ventilation with supplemental oxygen.

Quickly palpate the chest to confirm the findings of inspection. Check for symmetry of chest movement by placing the tips of your thumbs on the xiphoid process (the lower tip of the sternum) and spreading your hands over the lower rib cage. Both hands should move an equal distance with each breath. Apply slight pressure downward and inward on the rib cage. It may be easier to palpate for paradoxical movement in the chest wall rather than to see it on inspection, since muscle spasms usually keep the segment from moving dramatically. Also palpate for tenderness, subcutaneous emphysema, crepitation, and instability.

Use a stethoscope to auscultate for breath sounds (EMT Skills 13-5G). Listen to the breath sounds in the apices (top portions) and bases (bottom portions) of the lungs, comparing the left to the right side at each level. To assess each apex of the lung, place the stethoscope at the second intercostal space at the midclavicular line. Listen to each base at the fourth or fifth intercostal space in the midaxillary line. Listen during both inspiration and exhalation.

When listening to breath sounds, determine if the sounds are present and equal on both sides. Absent or diminished breath sounds on one side may indicate a serious lung or chest injury or bronchial obstruction.

If the breath sounds are absent or severely diminished on one side, quickly reassess the heart rate and quality, reassess respiratory rate and quality, assess for evidence of severe respiratory distress and hypoxia, and assess for jugular venous distention and tracheal deviation. Suspect a tension pneumothorax if the breath sounds are absent or severely diminished and the heart rate is increasing (tachycardia), the pulse is becoming weaker, the respiratory rate is increasing (tachypnea), ventilations are becoming more shallow, signs of respiratory distress are worsening, and signs of hypoxia are present.

A tension pneumothorax (a life-threatening condition) occurs when the injured lung is completely collapsed from air trapped in the pleural space. The pleural space continues to take in air and creates a high pressure, reducing the volume of the lung on the injured side. This pressure begins to shift over to the uninjured lung, compressing the heart, kinking the vena cava, and compressing the uninjured lung. This causes the signs and symptoms previously described. If the pressure is not released, the patient will rapidly deteriorate and become severely hypoxic.

**PATHOPHYSIOLOGY PEARLS**

Because of gravity, blood moves toward the feet and air travels toward the head. If the patient has suffered a pneumothorax (air trapped in the pleural space) and is standing or seated, the air will tend to collect in the top portion of the lungs (apex) near the clavicles. Thus the patient with a pneumothorax will likely have diminished breath sounds to the apex of the lungs early, whereas if the lung collapse is due to the presence of blood in the pleural space, breath sounds at the lower lobes of the lungs may be diminished early.
Assess the Abdomen

Inspect the abdomen for evidence of deformities, contusions, abrasions, penetrations, burns, lacerations, and any other evidence of trauma. These signs could indicate trauma to the abdomen, the possibility of underlying abdominal organ injury, and life-threatening bleeding into the abdominal cavity.

While inspecting the abdomen, look for discoloration around the umbilicus (navel) and in the flank areas (sides). This is a sign that blood has collected in the abdomen. Usually this is not seen until several hours after the injury. It takes an extremely large amount of blood in the abdomen to produce abdominal distention, in which the abdomen appears to be abnormally large or swollen. By the time this is seen in the patient, it is an indication that a significant amount of blood has been lost in the abdominal cavity.

Palpate each of the four quadrants of the abdomen with the pads of your fingers by placing one hand on top of the other and rolling the hands across the quadrant (EMT Skills 13-5H). Each quadrant should be quickly palpated once for tenderness, guarding (spasm of the abdominal muscles), and rigidity (hardness or stiffness from the contraction of the abdominal muscles). To get the most reliable exam, first palpate areas farthest from the pain.

Tenderness is a pain response elicited when the abdomen is palpated. If the patient is unresponsive, watch his face for a grimace while palpating. This would indicate pain on palpation. Also when palpating, feel if the abdomen is firm or soft. A firm or rigid abdomen is due to guarding. This is an indication of organ injury or irritation of the abdominal lining. A soft abdomen is a normal finding.

The Markle test, or heel jar test, is another way to assess for rebound tenderness and possible internal injury to abdominal organs. With the patient supine, strike the bottom of the heel sharply with your clenched fist, using enough force to shake and jar the abdomen (review Figure 13-19). If there is an existing irritation of the peritoneum (abdominal lining), for example by contents spilled from an injured or ruptured organ, the result of the heel strike will be a sharp pain to the abdomen. The responsive patient will report the pain; the patient who is responsive to pain will likely grimace.

PATHOPHYSIOLOGY PEARLS

Different signs and symptoms are produced by internal bleeding and by the spilled contents of ruptured organs. Blood in the abdominal cavity is not very irritating and will not produce serious pain, but it will cause the abdomen to become rigid or stiff. However, the peritoneum (abdominal lining) has a large number of sensory nerves that typically respond quickly and severely to irritating substances leaking from organs. Bleeding can occur behind the lining of the abdomen (retroperitoneal space). Since there are not many nerves located in this area, the bleeding and injury can be easily missed.
Assess the Pelvis

Inspect the pelvis (EMT Skills 13-5I) for any evidence of trauma: deformsities, contusions, abrasions, penetrations, burns, lacerations, or swelling. If the patient complains of pain or has obvious deformity to the pelvic region, you should suspect a pelvic injury. Do not palpate the pelvis if an injury is suspected.

Following inspection and palpation, check for “PMS”—distal pulses, motor function, and sensation:

- **Pulses**. Check distal pulses in all extremities. In the lower extremities, check the dorsalis pedis pulse. This is the pulse that is located on the top of the foot approximately midway between the toes and the ankle on the big toe side. Another distal pulse that could be assessed in the lower extremities is the posterior tibial pulse. This pulse is located behind the medial malleolus, the knob at the inner side of the ankle.

  When assessing for either pulse, bare the area where the pulse is to be felt. In the upper extremities, assess for a radial pulse. The radial pulse is located on the thumb side near the anterior base of the wrist.

  Determine if pulses are present in each extremity. Compare the strength of the pulses of each extremity. Absent or weak pulses could indicate poor perfusion from shock, a pinched or damaged artery from a bone injury, or a blood clot blocking circulation. When feeling for the pulse, also note the patient’s skin color, temperature, and condition in each extremity as an indication of perfusion.

- **Motor Function**. If the patient is able to obey commands, ask the patient to wiggle his toes and squeeze your fingers. Simply determine if the patient can move his fingers and toes.

- **Sensation**. In a responsive patient, touch a finger on one hand and ask the patient to identify what finger you are touching. Then pinch the hand and ask the patient to identify the extremity with pain. (Test both light touch and pain, since each of these stimuli is carried by a different nerve tract in the spinal cord.) Repeat this procedure on the other hand and then each foot, using the toes.

If the patient is not complaining of any pain in the pelvic region, or no deformsities are noted, place each hand on the iliac crest and gently compress the pelvis inward and downward. Also compress the symphysis pubis for any tenderness, facial grimace, or instability. Note any instability, crepitation, tenderness, or deformity.

**Assessment Tips**

A pelvic fracture can be associated with severe bleeding. Be prepared to treat hemorrhagic shock in a patient with a pelvic fracture.

Assess the Extremities

Assess first the lower, then the upper, extremities (EMT Skills 13-5J to 13-5N). Inspect and palpate the extremities for deformsities, contusions, abrasions, penetrations, burns, tenderness, lacerations, swelling, and any other evidence of trauma. Trauma to the extremities rarely produces life-threatening injuries. Major bleeding will be your major concern. Like the pelvis, a fractured femur may lead to profuse bleeding from the bone and surrounding blood vessels. Since bone and joint injuries are usually not life threatening, splinting in the critical patient must be conducted en route to the hospital and not at the scene. Too much time is lost when splints are applied at the scene of an incident.

If the patient is not complaining of any pain in the pelvic region, or no deformsities are noted, place each hand on the iliac crest and gently compress the pelvis inward and downward. Also compress the symphysis pubis for any tenderness, facial grimace, or instability. Note any instability, crepitation, tenderness, or deformity.

Assess the Posterior Body

With in-line spinal stabilization being maintained, roll the patient to inspect and palpate the posterior aspect of the body (EMT Skills 13-5O). With the patient positioned on his side, quickly inspect the posterior thorax, lumbar region, buttocks, and backs of the legs. Look for deformities, contusions, abrasions, punctures, burns, lacerations, swelling, or any other evidence of injury. Any open wound to the posterior thorax must be covered with an occlusive dressing.

If the patient is not complaining of pain along the vertebrae, lightly and gently palpate the vertebral column for any deformity and tenderness. Be extremely careful not to move the patient or cause excessive pain when palpat ing. This may jeopardize the in-line stabilization. If the patient is complaining of pain, assume that a spinal injury exists. Provide complete spinal immobilization.

With the patient on his side, place a backboard alongside him and roll him back down onto the backboard. Continue manual in-line stabilization until the patient is completely secured to the backboard.

Assess Baseline Vital Signs

In the rapid secondary assessment for the trauma patient, vital sign assessment follows the physical exam and precedes the history. However, if you have enough assistance and can be sure that in-line stabilization is being maintained by a trained person, these steps may overlap. For example, one EMT may be able to get vital sign measurements while the other conducts the physical exam, or vital signs and history may be taken at the same time.

The methods for assessing the vital signs were discussed in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” The vital signs are reviewed briefly here with notes about vital sign assessment for the trauma patient:

- **Breathing.** Assess the rate, tidal volume, and quality of breathing. Determine the quality of breathing as normal, shallow, labored, deep, or noisy. (See Table 13-5 regarding adequate and inadequate breathing.)
- **Pulse.** Assess the radial pulse in the adult and child patient and the brachial pulse in an infant less than 1 year of age. If the radial pulse is not present, assess the carotid pulse. If there is a carotid pulse (central pulse) but no radial pulse (peripheral pulse), or if the radial pulse is weak and rapid, the patient is likely to be suffering from shock (hypoperfusion).

**Assessment Tips**

A pulse that becomes very weak or disappears only when the patient inhales may indicate shock from blood loss, a tension pneumothorax, or pericardial tamponade.

If the patient is unresponsive, pinch the hand or foot and watch the response. It is important in the unresponsive patient to note the motor response associated with the painful stimulus applied to the extremity. Be careful when interpreting the response to pain applied to an extremity, since it may be the spinal cord returning the impulse and not the brain.

Injury to the femur is an exception to the rule that extremity injuries are not life threatening. Injury to the femur could result in severe bleeding within the bone and around the muscle and tissue in the leg. Therefore, injury to the femur is considered critical. If the thigh is discovered to be painful, swollen, or deformed and a femur fracture is suspected, immobilize the patient on a backboard and initiate prompt transport.

**Pathophysiology Pearls**

The sensation of light touch and the sensation of pain are carried by different nerve tracts within the spinal cord. It is possible that a patient who can feel light touch in an extremity may be unable to feel pain in that same extremity because of an incomplete injury of the spinal cord.

If the patient is complaining of pain along the spinal cord, continue manual in-line stabilization until the injury exists. Provide complete spinal immobilization. If the patient is not complaining of pain along the spinal cord, lightly and gently palpate the vertebral column for any deformity and tenderness. Be extremely careful not to move the patient or cause excessive pain when palpating. This may jeopardize the in-line stabilization. If the patient is complaining of pain, assume that a spinal injury exists. Provide complete spinal immobilization.
• **Skin.** The skin is assessed to determine the perfusion status of the patient. Inspect for pale or cyanotic nail beds and pale skin, oral mucosa, and conjunctiva. Feel the skin with the back of the hand for the temperature and condition. Pale, cool, clammy skin is a strong indication of poor tissue perfusion. A trauma patient with tachycardia (rapid pulse) and pale, cool, clammy skin should be assumed to be in shock.

Assess for capillary refill. A delayed capillary refill may indicate poor tissue perfusion and shock. However, cold exposure and other conditions may lengthen the capillary refill time, making it a less reliable sign of shock. Capillary refill alone cannot identify a shock patient. You must look at several different assessment findings to determine a shock state.

• **Pupil.** Quickly assess the pupils for size and reactivity by shining a light into the patient's eyes. Poor perfusion could cause the pupils to dilate and respond sluggishly to light, so this sign may be considered along with other indicators of shock. Head injury may cause the pupils to become unequal and unresponsive to light.

• **Blood pressure.** Take the blood pressure by auscultation. Determine the systolic and diastolic pressure. Two signs of serious blood loss and shock are narrow pulse pressure (the difference between the systolic and diastolic pressures) and hypotension (low blood pressure). If the blood pressure cannot be auscultated because of excessive noise at the scene, use the palpation method. Since palpation provides only the systolic pressure, pulse pressure cannot be determined by this method.

• **Pulse oximeter.** The pulse oximeter (Figure 13-28) can be applied to determine the level of oxygenation. Any SpO₂ reading less than 94% should heighten your suspicion that the patient is hypoxic. You must look for other evidence and a cause for the hypoxia. Closely assess the respiratory status, to include rate and tidal volume, to be sure that both are adequate. Be aggressive with airway management, initiation of positive pressure ventilation, and administration of oxygen in the hypoxic patient. Be careful when using the pulse oximeter in patients with suspected hypoperfusion or shock. You may not get a reading on the pulse oximeter or the reading may be erroneous because of the poor perfusion status and blood loss.

</tr>
</tbody>
</table>

![FIGURE 13-28](apply-a-pulse-oximeter-to-measure-the-artificial-blood-oxygen-level)
Hypoglycemia will be discussed in Chapter 20, “Acute Diabetic Emergencies.”

The vital signs should be reassessed and recorded every 5 minutes in the unstable patient. In the stable patient, the vital signs should be reassessed and recorded a minimum of every 15 minutes. Consider any trauma patient with a significant mechanism of injury to be unstable and assess vital signs every 5 minutes.

**PATHOPHYSIOLOGY PEARLS**

A narrowing pulse pressure (where the systolic and diastolic pressure readings get closer together) typically occurs when the amount of blood being ejected from the left ventricle decreases (systolic blood pressure measure) while the vessels constrict, decreasing their diameter and increasing resistance (diastolic blood pressure measure), in an attempt to increase the blood pressure.

**ASSESSMENT TIPS**

A palpated systolic blood pressure is an average of 7 mmHg lower than an auscultated systolic blood pressure.

**ASSESSMENT TIPS**

A systolic blood pressure that suddenly drops more than 10 mmHg only when the patient inhales may indicate shock from blood loss, a tension pneumothorax, or pericardial tamponade.

**PATHOPHYSIOLOGY PEARLS**

If a patient is bleeding, there are fewer red blood cells available to become oxygenated. This may produce a false high SpO₂ reading, since the remaining smaller number of red blood cells are oxygenated. However, there are not enough red blood cells carrying oxygen to the cells, and so the cells remain hypoxic.

**ASSESSMENT TIPS**

A normal blood glucose level in a nondiabetic patient who has had nothing to eat or has had no drink containing sugar or other carbohydrates for 8–12 hours is, on average, 80–90 mg/dL. It may range from 70–100 mg/dL. Shortly after a meal and for an hour or so, the nondiabetic BGL is usually 120–140 mg/dL.

**Obtain a History**

For a trauma patient, the history follows the physical exam and vital signs measurements. With two EMTs working together, the history can be conducted while the physical exam and vital signs are being assessed, or—if the patient is responsive—the history can be taken en route to the hospital. If the patient is unresponsive, you must attempt to get as much of the history as possible from family members or bystanders prior to leaving the scene.

---

**Blood Glucose Test**

The blood glucose level (BGL) is not considered one of the vital signs; however, any patient who presents with an altered mental status may be suffering from a low BGL (a low blood sugar level). This condition is referred to as hypoglycemia (low blood glucose). A test can be performed using a drop of the patient’s blood and an electronic glucometer to determine the blood glucose level. This may guide your treatment of the patient and provide you with an indication of whether to administer glucose to the patient or not. Refer to Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking,” to review blood glucose measurement.

![Figure 13-29](image) Use an electronic glucometer, such as this Roche Accu-Chek Aviva, to measure the blood glucose level.
History taking and questioning should not interfere with any assessment or treatment of life threats or delay transport of a critically injured patient.

Methods of obtaining a history were covered in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” The basic elements of the history are reviewed briefly here with notes about their relevance for the trauma patient with a significant mechanism of injury:

• **Signs.** *During your assessment, you are continuously inspecting for signs of trauma.* Deformities, contusions, abrasions, punctures, burns, lacerations, swelling, and indication of pain on palpation (tenderness) are all signs of blunt or penetrating trauma. It is important to correlate the sign with the mechanism of injury to focus your index of suspicion on specific possible injuries.

• **Symptoms.** *How do you feel? Do you hurt anywhere? What symptoms are you experiencing? (If the patient is unresponsive, ask bystanders if he complained of pain or any other symptoms before losing consciousness.)* The patient may complain of pain, light-headedness, weakness, dizziness, dyspnea, numbness, tingling, nausea, or many other symptoms associated with trauma. Any complaints of dyspnea, severe headache, chest pain, or abdominal pain should cause you to closely examine the related area for life-threatening injuries. For example, a patient who is complaining of dyspnea should be examined closely for possible life-threatening chest injuries such as a flail segment, open chest wound, or air in the chest cavity. Symptoms are gathered throughout assessment. Signs, symptoms, and mechanism of injury are the basis for emergency care provided to trauma patients.

• **Allergies.** *Do you have any allergies? Are you allergic to any medications?* For the trauma patient, gather information on allergies to medications that may be important for the medical facility staff to know about. Look for a medical tag that may identify an allergy.

• **Medications.** *Are you currently taking any medications?* In the trauma patient, it is not extremely important to gather extensive information regarding the prescription or over-the-counter medications the patient is currently taking. However, this information may help to provide a medical history in the unresponsive trauma patient, and some medications may alter the signs and symptoms expected in some conditions or may cause the patient to decompensate (succumb to shock) faster. For example, beta blocker drugs are frequently taken to control hypertension and heart rhythms. A beta blocker will slow the heart rate. A patient who is on a beta blocker and is in shock may not have the classic signs of shock, such as tachycardia or clammy skin. Also, this patient will not compensate well and will deteriorate more quickly.

**Assessment Tips**

If the patient is taking a beta blocker or calcium channel blocker drug, the heart rate may remain slower than expected in some conditions, such as shock. Therefore, the one significant sign of shock that might not be seen in this patient is tachycardia, because of the effects of the drugs.

Gather whatever information about medications you can, but do not expend any extra time at the scene to determine the patient’s medications. This information is not vital for the trauma patient.

• **Pertinent Past Medical History.** *Have you had any recent illnesses? Have you been seeing a doctor for any condition?* Quickly determine the medical history from the patient or, if the patient is unresponsive, from a family member. A patient with an existing medical condition may decompensate faster and exhibit altered signs and symptoms related to the past medical or surgical condition. Ask quickly about any past medical problems, trauma, or surgeries. Also, inspect the neck and extremities for a medical identification tag.

• **Last Oral Intake.** *When did you last eat or drink anything?* Find out from the patient or family member or knowledgeable bystander the last time the patient ate solid food or drank any liquids. If possible, determine the approximate amount. This information is important to the hospital staff if the patient needs anesthesia for surgery.

• **Events Leading to the Injury.** *How did the incident happen?* Asking the trauma patient how the accident or injury occurred can provide information about the mechanism of injury. Information from the patient or bystanders may shed additional light on the mechanism of injury, for example the height from which the patient fell. It is also important to determine why an accident occurred. Did the patient get dizzy and swerve off the road? Was the patient having chest pain that caused him to fall down the stairs? Did the patient lose consciousness before wrecking the car? A patient in an automobile crash who tells you that he was driving 90 mph because he was shot in the abdomen and was trying to get to the hospital has a clear mechanism of injury that provides you with suspicions of other injuries. Knowing what events led up to the accident or incident could also be helpful in determining if an illness exists in addition to the trauma.

**Prepare the Patient for Transport**

Normally, the critical trauma patient is prepared for transport simultaneously as the rapid secondary assessment is being conducted. Other EMTs and First Responder personnel should be preparing the backboard, head immobilization device, and stretcher. Following or simultaneously with assessment of the vital signs, the
patient is secured to the backboard with straps. The head is immobilized with a head immobilization device or blanket rolls and tape (Figure 13-30). The patient should then be transported to the cot and into the ambulance. (The history can be taken during this process or delayed to be taken in the ambulance.) Techniques for immobilization and transfer of the patient to the ambulance are covered in detail in Chapter 32, “Spinal Column and Spinal Cord Trauma,” and Chapter 6, “Lifting and Moving Patients.”

Once the patient is completely immobilized, transport should not be delayed. If any critical findings are present and the trauma patient is unstable, on-scene time should be limited to 10 minutes or less. See Table 13-11 for factors to consider as part of a decision for prompt transport. Bear in mind that prompt transport is key in survival of the critically injured patient.

To ensure the best chance of survival in certain situations, the trauma patient must be transported to an appropriate trauma center. The decision should be based on physiological criteria, such as blood pressure, respiratory rate, and Glasgow Coma Scale score; anatomical criteria, such as where the patient was injured; mechanism of injury; and special considerations, such as age and medical history. The Centers for Disease Control has developed the Guidelines for Field Triage of Injured Patients to assist EMS providers with making a decision regarding destination of transport. This protocol (Figure 13-31) provides objective criteria and recommendations for rapid transport to a trauma center.

Provide Emergency Care

In addition to the interventions that have been mentioned for each critical finding listed in this section, the information that follows provides overall advice about emergency care based on the rapid secondary assessment.

The entire rapid secondary assessment is typically conducted in a period of about 2–2½ minutes. This includes the head-to-toe assessment, baseline vital signs, and history. For this kind of patient, who is likely to be in critical condition, the head-to-toe assessment should identify any immediately life-threatening injuries and conditions, as well as any other less severe injuries or problems the patient may have.

A decision to rapidly transport the patient is made based on the findings of the rapid secondary assessment. Any of the critical findings summarized in Table 13-11 is an indication for prompt transport, with further treatment and continued assessment to take place en route to the hospital. However, life-threatening injuries and conditions must be appropriately managed as found at the scene prior to transport. In critical patients, splinting for suspected bone or joint injuries is not done at the scene because these injuries are not life threatening, with the exception of a suspected fracture to the pelvis or femur if adequate resources are available and transport is not delayed to apply the splint.

During transport, the life threats are reassessed while further evaluating the patient and providing care, as possible, for additional conditions or injuries that are not immediately life threatening.

If the patient’s condition is stable, emergency treatment for non-life-threatening conditions or injuries may be completed at the scene before transport. However, in a trauma patient with a significant mechanism of injury or a critical finding, a decision to transport rapidly is likely.

En route to the hospital, your priority is to continuously reassess the components of the primary assessment—mental status, airway, breathing, oxygenation, and circulation—plus vital signs and components of the rapid

**FIGURE 13-30** Prepare the patient for transport.
2011 Guidelines for Field Triage of Injured Patients

Measure vital signs and level of consciousness

- Glasgow Coma Scale ≤ 8
- Systolic Blood Pressure (mmHg) ≤ 90
- Respiratory Rate ≤ 10 or ≥ 29 breaths per minute, or need for ventilatory support (< 20 in infant aged < 1 year)

Assess anatomy of injury

- All penetrating injuries to head, neck, torso, and extremities proximal to elbow or knee
- Chest wall instability or deformity (e.g., flail chest)
- Two or more proximal long-bone fractures
- Crushed, deformed, mangled, or bumbled extremity
- Amputation proximal to wrist or ankle
- Pelvic fractures
- Open or depressed skull fracture
- Paralysis

Assess mechanism of injury and evidence of high-energy impact

- Falls
  - Adults: ≥ 20 feet (one story is equal to 10 feet)
  - Children: ≥ 10 feet or two to three times the height of the child
- High-risk auto crash
  - Intrusion, including roof: > 12 inches occupant side; > 18 inches any side
  - Ejection (partial or complete) from automobile
  - Death in same passenger compartment
  - Vehicle telemetry data consistent with a high risk of injury
- Auto vs. pedestrian/bicyclist thrown, run over, or with significant (≥ 20 mph) impact
- Motorcycle crash ≥ 20 mph

Assess special patient or system considerations

- Older Adults
  - Risk of injury/death increases after age 55 years
  - SBP ≤ 90 may represent shock after age 65
  - Low impact mechanisms (e.g., ground-level falls) may result in severe injury
- Children
  - Should be triaged preferentially to pediatric capable trauma centers
- Anticoagulants and bleeding disorders
  - Patients with head injury are at high risk for rapid deterioration
- Burns
  - Without other trauma mechanism: triage to burn facility
  - With trauma mechanism: triage to trauma center
- Pregnancy ≥ 20 weeks
- EMS provider judgment

Transport a trauma center, Steps 1 and 2 and attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the defined trauma system.

Transport to a trauma center, which, depending upon the defined trauma system, need not be the highest level trauma center.

Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.

When in doubt, transport to a trauma center.

Find the plan to save lives, at www.cdc.gov/fieldtriage

FIGURE 13-31 Guidelines for Field Triage of Injured Patients, Centers for Disease Control, 2011.
secondary assessment focused on the patient’s injuries. You will also reassess the effectiveness of your interventions. This is known as a reassessment and is described in Part 4 of this chapter.

You must set priorities for management of critical injuries and conditions both at the scene and throughout the transport to the hospital. If a patient has suffered blunt trauma to the face with significant bleeding in the upper airway, the EMT caring for the patient in the back of the ambulance is most concerned with maintaining a patent airway. This can only be done with continuous suction. In addition, the EMT must reassess the breathing and perfusion status and reassess vital signs. Management of the airway takes precedence over any other condition and over any additional assessment.

**Trauma Score**

A trauma score is a numerical way to identify the severity of trauma. Many EMS systems use the scoring system as a means to communicate the severity of the patient to the receiving facility. You should be familiar with the trauma scoring system used in your region and familiar with the elements of that scoring system.

The Revised Trauma Score (Table 13-12), which includes the Glasgow Coma Scale, is one type of scoring system used. A number is assigned to each parameter being assessed. The numbers from each subset are totaled and a score is derived for that particular patient. The lower the score, the more severe the patient’s condition.

The major components of the trauma score are:

- Respiratory rate
- Systolic blood pressure
- Glasgow Coma Scale (GCS) score

Report and document the findings of the Revised Trauma Score. This information is extremely useful to the receiving facility for purposes of reassessment.

---

**MODIFIED SECONDARY ASSESSMENT: TRAUMA PATIENT WITH NO SIGNIFICANT MECHANISM OF INJURY, ALTERED MENTAL STATUS, MULTIPLE INJURIES, OR CRITICAL FINDING (STABLE)**

On the prior pages, we discussed how to conduct the secondary assessment when you have determined that the patient has a significant mechanism of injury, altered mental status, multiple injuries, or a critical finding. Here we will discuss the trauma patient whose mechanism of injury is not significant, who is alert and oriented, who does not have multiple injuries, and for whom no critical findings are present. If you are ever in doubt as to what assessment to perform, err to benefit the patient and perform the rapid secondary assessment to avoid missing injuries.

**Perform a Modified Secondary Assessment**

Consider a patient whose injury is a laceration to one finger that resulted from a slip of the knife while cutting a tomato. The finger may be bleeding profusely, but the mechanism of injury is not significant—that is, it is a mechanism that does not lead you to suspect additional injuries or problems, the patient is alert, and no critical findings are present.

For this patient, a complete head-to-toe rapid secondary assessment is not necessary or appropriate. Instead, you conduct a modified secondary assessment—an exam that focuses primarily on the injury site, in this case the injured finger. You use the same techniques as in a secondary assessment—inspecting and palpating for deformities, contusions, abrasions, punctures, burns, tenderness, lacerations, and swelling—but you assess just the specific localized site of the injury. For the patient with the cut finger, you have already controlled the bleeding as part of the primary assessment, and now you conduct the modified secondary assessment to ensure that there is no further injury to the patient’s hand or arm, such as a burn or a bone or joint injury.

Another example is a suspected bone or joint injury. Earlier, it was stated that injuries to the extremities are seldom life threatening, and that complete assessment and treatment of such injuries for a critical trauma patient would not take place at the scene. Instead, treatment would be carried out in the ambulance en route to the hospital if time and care of the patient’s more serious problems permit. However, for the patient who has no significant mechanism of injury, is alert and oriented, has no multiple injuries, and has no critical findings, but presents with indications of a possible fracture or other injury to a bone or joint, full assessment and splinting of the injured extremity would be carried out at the scene before transport to the hospital.

For instance, a high school student is playing volleyball and jumps up for the ball. She lands on the lateral aspect of her right ankle with her leg in a twisted position. You are called to the scene. The patient is complaining of severe pain to her ankle. You perform a scene size-up and brief primary assessment and determine that no significant mechanism of injury has occurred, the patient is alert and oriented, and no multiple or critical injuries exist. You would immediately focus in on the ankle injury and inspect and palpate the entire

#### Revised Trauma Index

The Trauma Score is a numerical grading system for estimating the severity of injury.¹ The score is composed of the Glasgow Coma Scale (reduced to approximately one-third total value) and measurements of cardiopulmonary function. Each parameter is given a number (high for normal and low for impaired function). Severity of injury is estimated by summing the numbers. The lowest score is 0 and the highest score is 12.

### Operational Definitions

#### Respiratory Rate

Number of respirations in 15 seconds; multiply by 4

#### Systolic Blood Pressure

Systolic cuff pressure, either arm—auscultate or palpate

- No pulse—no carotid pulse

#### Best Verbal Response

- Arouse patient with voice or painful stimulus

#### Best Motor Response

- Response to command or painful stimulus

#### Projected estimate of survival for each value of the Trauma Score based on results from 1,509 patients with blunt or penetrating injury²

### Source

2 Endorsed by the American Trauma Society.
extremity. Then you would immobilize the ankle while still at the scene.

To assess an upper or lower extremity when a bone or joint injury is suspected, inspect for deformity (such as angulation to a bone where no joint exists), contusions, and swelling. Palpate by placing your hands around the entire extremity so that the thumbs come together on the anterior surface and the little fingers are on the posterior surface. Your thumbs and fingers should never lose contact with the extremity during the palpation. Begin at the most proximal point (closest to the heart) and palpate to the most distal point (farthest from the heart), noting any deformity, swelling, tenderness, or crepititation.

Following inspection and palpation, check the distal pulses, motor function, and sensation. Always assess distal pulses, motor function, and sensation both before the injury is splinted (to detect any impairment of function caused by the injury) and after the injury is splinted (to detect any improvement or deterioration of function resulting from the intervention). Be sure to document this assessment on the prehospital care report.

**Obtain Baseline Vital Signs and History**

Once the modified secondary assessment is completed, assess the baseline vital signs and obtain the history. Then provide emergency care for the injuries found and prepare the patient for transport. While en route to the hospital, reassess the airway, breathing, and perfusion; reassess vital signs; and check the effectiveness of the emergency care provided.

**Perform a Rapid Secondary Assessment if Indicated**

Although the modified secondary assessment is usually appropriate for a trauma patient with no significant mechanism of injury, no altered mental status, no evidence of multiple injuries, and no critical finding, occasionally it is wise to conduct a full head-to-toe secondary assessment.

One such instance would be when you undertake a modified secondary assessment in a patient with no significant mechanism of injury but you develop a suspicion that more injuries may exist than what the patient is complaining of, or the patient begins to deteriorate. In this case, immediately conduct a complete secondary assessment.

Another instance would be when you are conducting a modified secondary assessment on a patient and you make a critical finding. Immediately perform a secondary assessment and consider prompt transport. For example, you arrive on the scene and find a patient lying on the kitchen floor complaining of pain to his left hip. He says that he slipped on some water and fell. The mechanism of injury is not significant, and the primary assessment does not reveal any critical findings. Therefore, you decide to perform a modified secondary assessment on the left hip, area, extending to the pelvis and both lower extremities. When you begin to palpate the pelvis, the patient complains of severe pain and you feel instability and crepitation. A pelvic injury is considered a critical finding, so you quickly conduct a secondary assessment, assess baseline vitals, and prepare the patient for immediate transport. En route, you reassess airway, breathing, and perfusion; reassess vital signs; complete the history; and reassess the abdomen, pelvis, and lower extremities.

Another kind of patient with no significant mechanism of injury and no critical findings, who nevertheless must have a complete secondary assessment, is the patient suffering from multiple injuries each of which, by itself, would not be considered critical. The patient may have multiple minor soft tissue injuries. Or the patient may have suspected multiple fractures to the extremities. In either situation, the multiple injuries may indicate a more significant mechanism of injury than was first suspected. The multiple injuries may also, cumulatively, be causing significant internal or external blood loss and shock. For this patient, perform a head-to-toe assessment and, if these are critical findings, consider prompt transport.

Remember: If there is any question in your mind as to what assessment to perform on a patient—the limited modified secondary assessment versus the complete secondary assessment—err to benefit the patient and conduct the complete secondary assessment.
A medical patient has not suffered from any type of injury or trauma, but instead is experiencing signs and symptoms related to a disease process or condition affecting the body’s organs or systems.

As was true for the trauma patient, you will perform the secondary assessment on the medical patient (Figure 13-32 □) immediately following the primary assessment. Life-threatening conditions of the airway, breathing, oxygenation, and circulation will have already been managed as part of the primary assessment. Further emergency care will be based on your findings from the secondary assessment.

First, you will categorize the medical patient in one of three ways: as alert, oriented, and responsive; or as not alert, disoriented, and responsive to only verbal or painful stimuli; or as unresponsive. For ease of categorization, the alert, oriented, and responsive patient will be referred to as “responsive” and the patient who is not alert, is disoriented, is responsive to verbal or painful stimuli, or is unresponsive will be referred to as “unresponsive.”

### ASSESSMENT TIPS

A responsive medical patient is one who not only responds to your questions and commands but responds appropriately. If the patient responds, but not appropriately, consider the patient’s responses to be unreliable and conduct a rapid secondary assessment.

There are two key differences in the way you will conduct the secondary assessment for the responsive medical patient versus the unresponsive medical patient.

The first difference is in the sequence of steps. For the responsive medical patient, you will gather the history from the patient first, then conduct the physical exam and obtain the vital signs. The history comes first for the responsive medical patient for two reasons: (1) the most valuable information on a medical condition in the prehospital setting usually comes from what the patient can tell you about how he feels; and (2) it is important to get information from the patient before he, possibly, becomes unresponsive. For the patient who is already unresponsive when you arrive on the scene, the physical exam and vital signs will come before the history, which will need to be gathered, to the extent possible, from family members or bystanders.

The second difference is in the kind of physical exam you will conduct. For the responsive medical patient, you will conduct a modified secondary assessment—an exam that is focused on the patient’s chief complaint, signs, and symptoms. For the unresponsive medical patient, you will conduct a rapid secondary assessment—the quick head-to-toe assessment that is similar to the rapid secondary assessment conducted on the trauma patient. You will look for signs relating to the patient’s medical condition as well as any signs of possible trauma that may have been missed earlier.

As the next chart reveals, the secondary assessment for an unresponsive medical patient is similar to the secondary assessment for a trauma patient with significant mechanism of injury because, in both instances, you first need to examine the whole body for information the patient cannot tell you. The modified secondary assessment for a responsive medical patient (the majority of your medical calls) begins with the history, followed by a physical exam focused on the patient’s chief complaint, signs, and symptoms.
An altered mental status in a medical patient should be considered critical. You must perform a rapid secondary assessment, followed by prompt transport, continued assessment, and emergency care en route to the hospital.

Attempt to gain as much information from the scene as possible. Note the patient's medications, both prescribed and over-the-counter; any evidence of drugs or alcohol; signs that the patient may have been sick for a period of time; and the condition of the place in which the patient was found. Look at how the patient is dressed, where he was found, and what he may have been doing prior to the emergency. If you walk into the scene and find an oxygen tank or concentrator in the living room, you are likely to suspect that the patient has a history of emphysema, chronic bronchitis, or some other type of respiratory condition. A patient in a hospital-type bed usually has a chronic illness or severe debilitating disease.

Make use of other sources of information. Question bystanders, family members, or other relatives or friends. The patient may have been complaining of symptoms prior to the altered mental state or unresponsiveness. Look for a medical identification tag on the patient as evidence of a chronic illness.

Perform a Rapid Secondary Assessment for the Medical Patient

Perform a rapid medical assessment on the unresponsive patient to determine the possible nature of the medical illness. The patient's airway, breathing, oxygenation, and perfusion status will have been assessed and managed during the primary assessment. As you perform the rapid secondary assessment, reassess the airway, breathing, oxygenation, and circulation status and manage these or any additional life-threatening problems immediately.

Like the rapid secondary assessment for the trauma patient, the rapid secondary assessment for the medical patient should be conducted systematically, beginning at the head and covering all major portions of the body (EMT Skills 13-6). The techniques of inspection, palpation, and auscultation are used to search for any signs of abnormality or dysfunction.

Assess the Head

Inspect the head for any evidence of trauma (EMT Skills 13-6A). You may not initially expect to find trauma, because of a lack of mechanism of injury; however, the patient may have fallen several hours, days, or even weeks prior to the onset of the signs, symptoms, or unresponsiveness. Inspect for contusions, lacerations, depressions, abrasions, punctures, and any other evidence of trauma. Palpate the head for any deformities.

Quickly inspect inside the mouth for pale mucosa, bleeding, secretions, or vomitus. Reassess the airway and ensure that it is patent. Inspect the nose and ears for fluid discharge or blood. Quickly inspect the pupils for equality, size, and reactivity. Unequal pupils may indicate a stroke or possible head injury. Pupil size and reactivity may provide evidence of drug overdose, poisoning, hypoxia, or adverse environmental conditions. Inspect for a droop to one side of the face.

**ASSESSMENT TIPS**

A pale oral mucosa (inside the mouth) may indicate that the medical patient has been losing blood over a long period of time.
Assess the Neck

Inspect the neck for jugular vein distention (EMT Skills 13-6B). In the medical patient, JVD may be a sign of right-sided heart failure or late left-sided heart failure. You might find JVD associated with complaints of chest pain, dyspnea, or severe fatigue and weakness. The patient may also complain of (or you should ask about) the inability to breathe or shortness of breath while lying flat, which is termed orthopnea.

**Assessment Tips**

If you see jugular vein distention, also inspect the veins in the hands. They will be engorged from an increase in the venous blood volume and pressure.

Inspect the neck for excessive accessory muscle use. If the muscles in the neck bulge and become very prominent during inhalation, respiratory distress should be suspected. Reassess the adequacy of breathing.

**Pathophysiology Pearls**

In labored breathing, the neck muscle that is used as an accessory muscle for breathing lifts the sternum higher than normal. By doing so, it is attempting to increase the thorax to a greater-than-normal size, thus increasing the negative pressure inside and allowing more air to flow into the lungs.

While inspecting the neck, look for a medical identification necklace with pertinent information about the patient inscribed on the back (or the medical ID tag may, instead, be worn as a bracelet) (EMT Skills 13-6C). The information on the tag may provide you with an indication of the patient’s condition.

Check for a tracheostomy tube at the base of the neck. Because the patient breathes through this tube, secretions and mucus could block the tube, causing an airway obstruction.

Assess the Chest

Inspect the chest for adequate rise and fall, retraction of the intercostal muscles, and symmetrical movement (EMT Skills 13-6D). An inward pulling of the muscles between the ribs during inhalation indicates respiratory distress. In a patient who is unresponsive or has a deteriorating mental status, begin positive pressure ventilation with supplemental oxygen if retractions are noted and the respiratory rate or tidal volume is inadequate.

Look for open-heart surgery scars and evidence of implanted cardiac devices such as a pacemaker or automated internal cardiac defibrillator (Figure 13-33). These will provide a history of cardiac disease even if the patient is unable to respond to your history questions.

Quickly auscultate the breath sounds at the second intercostal space at the midclavicular line and at the fourth or fifth intercostal space at the midaxillary line. Compare the breath sounds from side to side. Determine if the breath sounds are present or absent, equal or unequal, clear or noisy.

Noisy breath sounds are not normally heard in the lungs upon auscultation. These sounds are a possible critical (unstable) finding:

indication of a condition the patient may be suffering. The sounds that you may hear are:

- **Crackles.** Also known as rales, these are a fine crackling sound on inhalation similar to hair being rubbed together close to your ear. This is an indication of fluid in and around the alveoli and the terminal end of the bronchiole. Crackles are also heard as the alveoli “pop” open to allow air to pass through. Patients whose left ventricle is failing and who are in congestive heart failure may experience an increase in the pressure in the pulmonary vessels in the lungs. This increase may force fluid out of the capillaries and force the fluid around or into the alveoli. Another condition in which crackles may be heard is pneumonia, when puslike fluid collects in the alveoli.

**PATHOPHYSIOLOGY PEARLS**

The pressure inside the pulmonary capillaries (capillaries in the lungs) is very low. An increase in pressure inside the pulmonary capillaries may force the plasma portion (primarily water) of the blood out of the capillary and into the space between the capillary and the alveolus as well as into the alveolar sac. This may interfere with gas exchange and lead to hypoxia. It will also produce the crackle sound heard on auscultation. □

### Critical (Unstable) Findings: The Chest

</tr>
</tbody>
</table>

| Critical Finding: | Wheezing upon auscultation |

- **Wheezing.** Wheezing is heard as a musical-type sound on inhalation and exhalation. It is an indication that there is a higher resistance in the bronchioles with restricted airflow. The higher resistance may be caused by constriction of the smooth muscle surrounding the bronchiole and swelling and inflammation within the bronchiole. This commonly occurs in asthma, allergic reactions, and emphysema.

**Assess the Abdomen**

Inspect the abdomen for any abnormal distention or discoloration (EMT Skills 13-6E). Look for evidence of scars from previous surgeries. Palpate for tenderness, rigidity, or pulsating masses. A rigid, distended, or tender abdomen is a sign of possible internal bleeding, perforation of an organ, or infection. An aortic aneurysm, which is a weakened area of the abdominal aorta, may produce a palpable pulsating mass in the midline of the abdomen.
You can also assess for rebound tenderness, which indicates the lining of the abdomen, the peritoneum, is irritated. The irritation may result from leakage of a substance from a ruptured organ or from an infection of the peritoneum. This is referred to as peritonitis. To assess for rebound tenderness, you can press down firmly on the abdomen and then suddenly release your hand. If the patient complains of pain or grimaces, you could assume the patient has rebound tenderness and peritonitis. Since many patients will complain of pain before you even press down, the test may not provide much information about the abdomen. Perform the Markle test if the patient is able to stand or the heel jar test if the patient is unable to stand (review Figures 13-18 and 13-19). 

Assess the Extremities
Note any excessive peripheral edema (swelling around the hands, feet, and ankles). Excessive edema could indicate congestive heart failure, fluid overload, or a clot blocking a vein in that extremity (EMT Skills 13-6F). Also assess the extremities for pulses, motor function, and sensation (EMT Skills 13-6G and 13-6H). Assess the radial and dorsalis pedis pulses. Check motor function and sensation by pinching the hands and feet. Note the patient’s response. Look for a medical identification tag around the wrist or ankle.

Critical (Unstable) Findings: The Pelvic Region

<table>
<thead>
<tr>
<th>Critical Finding</th>
<th>Possibility</th>
<th>Emergency Care</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lower quadrant abdominal pain in the pelvic region</td>
<td>Ectopic pregnancy with bleeding within the abdominal cavity</td>
<td>Rapid transport upon recognition. Establish an airway, begin positive pressure ventilation at 10–12/minute if respiratory rate or tidal volume is inadequate, and administer oxygen if indicated</td>
</tr>
<tr>
<td>Tenderness on palpation</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Female patient in childbearing years with history of missed period (patient may present with vaginal bleeding)</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Assess the Pelvic Region
Look for signs of incontinence. Inspect and palpate for distention or tenderness. This is most significant in the female patient of childbearing age who could have an ectopic pregnancy. If a female patient complains of abdominal pain, usually isolated to the lower quadrants, has a history of a missed menstrual period, and exhibits signs and symptoms of poor perfusion, suspect an ectopic pregnancy—a surgical emergency requiring prompt transport. Note that the history of a missed period may be unreliable.

Assess the Posterior Body
Inspect and palpate the back for discoloration, edema, and tenderness. Edema to the sacral region may be from fluid collection associated with congestive heart failure.
Assess for edema (collection of fluid in the tissues under the skin) to the sacral region, called sacral edema, in patients who are bedridden and have their legs level with the heart. Excess fluid in patients who are mostly in a seated position and dangle their legs, or those who are moving about, will collect in the hands, ankles, and feet rather than in the sacral region.

Assess Baseline Vital Signs

In the secondary assessment for a medical patient who is not alert, is disoriented, is responding to verbal or painful stimuli, or is unresponsive, vital sign assessment follows the physical exam and precedes the history. Remember, however, that with EMT partners working together, some of these steps can be done simultaneously.

The methods for assessing the vital signs were discussed in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” The vital signs are reviewed briefly here, with notes about vital sign assessment for the medical patient who is not alert, is disoriented, is responding only to verbal or painful stimuli, or is unresponsive.

- **Breathing.** Tachypnea (rapid breathing) may indicate a central nervous system disorder, respiratory distress, cardiac problem, anxiety, poisoning, overdose, high blood sugar level, abdominal disorder, or a pulmonary problem. Abnormal respiratory patterns may be seen in patients with central nervous system disorders like stroke, poisoning, overdose, and diabetic emergencies.

**ASSESSMENT TIPS**

Abnormal respiratory patterns typically do not allow for adequate breathing. Assess the patient carefully to ensure the respiratory rate and tidal volume are adequate.

- **Pulse**
- **Skin**
- **Pupils.** Pupillary signs are important to document in the unresponsive patient. Note the size, equality, and reactivity to light.
- **Blood pressure**
- **Pulse oximeter**

The vital signs should be reassessed and recorded every 5 minutes in the unresponsive medical patient.

**PATHOPHYSIOLOGY PEARLS**

When oxygen attaches to hemoglobin on the red blood cell, it turns the molecule red. The pulse oximeter measures oxygen saturation by reading the redness of hemoglobin. Carbon monoxide (CO) attached to the hemoglobin also turns it red. Thus, the SpO2 reading will be inaccurately high in a patient with carbon monoxide poisoning, even though that patient’s cells are truly hypoxic.

**Blood Glucose Test**

Any patient who presents with an altered mental status may be suffering from a low blood glucose (sugar) level, referred to as hypoglycemia. As noted earlier, a test can be performed using a drop of the patient’s blood and an electronic glucometer to determine the blood glucose level. This may guide your treatment of the patient and provide an indication of whether to administer glucose to the patient. Hypoglycemia will be discussed in more detail in Chapter 20, “Acute Diabetic Emergencies.”

**ASSESSMENT TIPS**

It is important to determine the true last oral intake when testing the blood glucose level, because it will determine whether the reading is normal or not. Shortly after a meal or carbohydrate intake, the blood glucose level in the nondiabetic patient will be 120–140 mg/dL. A fasting (8 to 12 hours without food) blood glucose in the diabetic patient may be 120–140 mg/dL.

**Position the Patient**

A patient with a severely altered mental status or who is unresponsive most typically cannot protect his own airway. Secretions, mucus, blood, or vomitus can easily be aspirated into the lungs. To avoid the potential for aspiration, place the patient in the recovery position, also known as the coma position—a modified left lateral recumbent position—as you prepare the patient for transport (Figure 13-35). In this position, the secretions, blood, mucus, or vomitus will flow out of the mouth and not into the patient’s lungs. You must still have a suction device available to assist with clearing the airway, if necessary. If the patient needs to be ventilated, keep him in a supine position. It is very difficult to ventilate a patient on his side with a bag-valve mask or pocket mask.

**FIGURE 13-35** Position the unresponsive medical patient in the recovery position to protect the airway and prevent aspiration of secretions, blood, or vomitus.
Obtain a History

Methods of obtaining a history were covered in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” For the disoriented, severely altered mental status, or unresponsive patient, it is necessary to gain as much information as possible from any family members, friends, and bystanders at the scene (Figure 13-36 ■). The history is a quick method for obtaining limited but extremely important information. Because the patient has an altered mental status, a more detailed history that goes beyond this is not pursued. The following is a review of the history for the unresponsive medical patient:

- **Signs.** Signs will be revealed in the physical exam and vital signs assessment. As you conduct your rapid medical assessment and find specific signs, it may be necessary to ask the people at the scene relevant questions regarding the complaints of the patient. For example, if you find unequal pupils, it would be appropriate to ask those at the scene: Was the patient complaining of a headache, weakness, numbness, or paralysis in the extremities?

- **Symptoms.** Was the patient complaining of any symptoms prior to becoming unresponsive? Was the patient complaining of:
  - Shortness of breath?
  - Chest pain or any other type of pain?
  - Severe headache?
  - Light-headedness, dizziness, or faintness?
  - Severe itching?
  - Feeling excessively cold or hot?
  - Abdominal pain or pain in the lumbar region?

*If the patient was complaining of a particular symptom, try to determine from those at the scene:*
  - Was the onset sudden or gradual?
  - Did anything provoke the symptom?
  - How severe was the symptom?
  - How long was the patient complaining of the symptom?
  - Where exactly was the symptom felt?
  - Was anything done or taken to relieve the symptom?

![FIGURE 13-36] Prepare the patient for transport. Obtain a history from any bystanders, family, or friends of the unresponsive patient.
Events leading to the present illness. What was the patient doing prior to the onset of the unresponsiveness? What were his signs or symptoms? This is useful in trying to rule out trauma as the cause for the unresponsiveness.

Provide Emergency Care

Following the secondary assessment, you will provide emergency care based on the signs, symptoms, and history gathered. Supplemental oxygen should be administered based on the SpO2 reading, signs and symptoms of hypoxia, hypoxemia, heart failure, poor perfusion, respiratory distress, and complaint of dyspnea and not based solely on the condition. The routine use of high-concentration oxygen for every patient is no longer recommended.

Make a Transport Decision

Altered mental status in a medical patient is considered to be a critical finding. Transport should be prompt. However, life-threatening injuries and conditions must be appropriately managed at the scene prior to transport. During transport, closely monitor the airway, breathing, oxygenation, and circulation status. Reassess vital signs every 5 minutes. Following any intervention that you provide, check for a change in the patient's condition. If at any time the patient regains responsiveness, perform a secondary assessment and reevaluate the history.

RESPONSIVE MEDICAL PATIENT WHO IS ALERT AND ORIENTED

In the responsive medical patient who is alert and oriented, closely assess the history of the present illness. You do this mainly by asking the patient a series of questions. In the medical patient, the history should be the baseline for gathering information. It is often desirable to collect additional information from the history (refer to Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking”). With the responsive medical patient, you can add the OPQRST questions to the history to gain as complete a picture as possible of the illness the patient is experiencing. The manner in which you conduct the modified secondary assessment and provide emergency care will be based on the information you gather from the OPQRST and other history questions.

Assess Patient Complaints: OPQRST

OPQRST was discussed in detail in Chapter 11, “Baseline Vital Signs, Monitoring Devices, and History Taking.” It is a mnemonic for the questions you should ask...
when assessing the patient’s chief complaint or major symptoms like pain, as follows:

- **Onset.** When and how did the symptom begin?
- **Provocation/palliation.** What makes the symptom worse? What makes it better?
- **Quality.** How would you describe the pain?
- **Radiation.** Where do you feel the pain? Where does the pain go?
- **Severity.** How bad is the symptom?
- **Time.** How long have you had the symptom?

**Assessment Tips**

It is crucial to determine the exact time of onset of the first sign of weakness, slurred speech, numbness, paralysis, facial droop, or other signs of stroke and report it to the emergency department or receiving medical facility. You may be the only person who can collect this vital information at the scene from relatives, friends, or bystanders. It may make a critical difference in stroke and cardiac treatment once at the hospital.

**Complete the History**

You will have gained information about the patient’s symptoms in response to the OPQRST questions. Information about the patient’s signs will be gained during the physical exam and vital signs measurements. To complete the history, determine the patient’s allergies, medications, pertinent past medical history, last oral intake, and events leading to the present illness, as described in detail in Chapter 11 and earlier in this chapter for the unresponsive medical patient. Consider obtaining additional information in the history that might be helpful in determining the patient’s condition and in the continuum of care once at the medical facility.

**Perform a Modified Secondary Assessment**

For the responsive medical patient who is alert and oriented, the physical exam comes after the history. The physical exam may be more focused, or it may be a complete head-to-toe secondary assessment, depending on the patient complaint and suspected body systems involved. For example, if a patient is complaining of nontraumatic chest pain, possibly related to a heart problem, you would focus the exam on the pupils, conjunctiva, oral mucosa, neck, chest, abdomen, posterior body, and extremities. You would palpate the patient’s head, inspect inside the ears and nose, and palpate the pelvis and symphysis pubis. However, if the patient’s signs and symptoms are not specific enough to make a decision about what areas to focus on—for example, a complaint such as “I just don’t feel well”—you should perform a complete head-to-toe secondary assessment.

**Assess Baseline Vital Signs**

Obtain the breathing rate and quality; pulse rate and quality; skin temperature, color, and condition; capillary refill; pupil size and reactivity; blood pressure; and SpO2 reading.

Critical findings and interventions would be the same as those that were listed for the medical patient who is not alert, is disoriented, responds only to verbal or painful stimuli, or is unresponsive.

**Provide Emergency Care**

Emergency care provided to the patient will be based on the information gathered from the medical assessment and in consultation with medical direction. General care involves maintaining a patent airway, administering oxygen if indicated, and assisting ventilation, if necessary.

**Make a Transport Decision**

For a patient whose condition is not critical, the patient can be prepared for transport following the secondary assessment and provision of any required emergency care at the scene. If the patient’s condition is critical, this procedure can be expedited by having one EMT partner begin preparing the patient for transport while the other is completing the assessment. Once on-scene management of life-threatening conditions has been accomplished—such as ensuring a patent airway or providing positive pressure ventilation with supplemental oxygen if breathing is inadequate—the critical medical patient should be transported promptly with additional assessment and emergency care provided en route. Review Table 13-8 for the criteria for immediate transport. Prompt transport is the key to survival of the critical patient.

During transport, reassess the airway, breathing, and pulses. Take the vital signs every 5 minutes in the critical patient or unstable patient and every 15 minutes in the noncritical or stable patient. On every patient, assess the effectiveness of the interventions provided. For example, make sure that oxygen is being titrated to achieve an SpO2 reading of at least 94%. You should develop a pattern:

1. Assess
2. Intervene
3. Reassess

In the medical patient, you must rely heavily on the complaints of the patient and the signs and symptoms found during the secondary assessment to proceed with emergency care. You are not required to diagnose a medical condition or disease process but rather to recognize significant signs and symptoms and, based on these findings, provide care to manage life threats. Whenever you are in doubt or whenever local protocols require it, consult with medical direction prior to providing care.
The **reassessment** (Figures 13-38 and 13-39) is conducted following the secondary assessment. Reassessment is most often performed in the ambulance, continuously, until care of the patient is transferred to hospital personnel (EMT Skills 13-7). If there is a delay in arrival of an ambulance to transport the patient—for example, when the EMT is performing a first-response function or emergency care when off duty, when multiple patients require dispatch of additional ambulances, or when the patient is entrapped or requires extrication—reassessment may begin at the scene and continue in the ambulance.

**PURPOSES OF THE REASSESSMENT**

The purposes of the reassessment are to determine any changes in the patient’s condition and to assess the effectiveness of your emergency care. It should be performed on both the trauma and the medical patient, whether the patient is responsive or unresponsive, stable or unstable. If during the reassessment you identify a critical patient condition, you should provide immediate care to correct the problem. For example, as you perform the assessment you note that the patient’s breathing depth and quality have become inadequate. You would intervene immediately to begin positive pressure ventilation with supplemental oxygen.

If this is a trauma patient, you would repeat the rapid secondary assessment looking for the possible cause of the deterioration of the patient. Does the patient have signs of pneumothorax (air in the chest cavity, possibly from a damaged lung)? Did the occlusive dressing over an open chest wound become clotted, not allowing air to escape? Does the patient have a possible head injury? The rapid assessment should identify any signs and symptoms that may identify the possible cause of the patient’s condition.

The main objective is to intervene and provide the necessary emergency care for the life-threatening injuries or conditions, followed by reassessment. Remember that your routine should be as follows:

1. Assess
2. Intervene
3. Reassess

The reassessment must be performed on all patients. The three basic reasons for performing a reassessment are:

1. To detect any change in the patient’s condition
2. To identify any missed injuries or conditions, especially those that are life threatening
3. To adjust the emergency care as needed

**Detect Any Change in Condition**

Rapid changes in the patient’s condition can occur in the prehospital setting. Therefore, it is always necessary to look for signs and symptoms indicating deterioration as well as signs of improvement. Rapid deterioration is commonly due to continued blood loss, airway compromise, inadequate breathing or oxygenation, poor perfusion, or brain injury. These areas are the focus of the reassessment.
Identify Any Missed Injuries or Conditions

Many times the primary and secondary assessments are conducted in poor environmental conditions that limit the EMT’s ability to assess adequately. Extremely dark environments, for example, may limit your ability to see signs of injury. Noisy conditions, such as a hostile crowd or a busy highway, may interfere with your ability to hear breath sounds or patient complaints. Rain, bright sunshine, high winds, unstable vehicles, threats of explosion, smoke, or other conditions commonly reduce the effectiveness of assessment at the scene. The reassessment provides the opportunity to reassess for injuries or conditions once the patient is in a more stable and favorable environment, which is most likely the patient compartment of the ambulance.

If the patient’s condition improves, he may begin to complain of other symptoms. You can then conduct a secondary assessment relevant to the areas of the new complaint, looking for additional signs of injury or illness.

Adjust the Emergency Care

The reassessment allows you to reassess the effectiveness of the emergency care that you are providing. For example, you may have placed a nonrebreather mask with oxygen flowing at 15 lpm on a patient who was complaining of shortness of breath and exhibited signs of severe hypoxia. During the reassessment, you determine that the patient’s breathing depth has become extremely shallow, so you remove the nonrebreather mask and begin positive pressure ventilation at 10–12/minute with supplemental oxygen.

The steps of the reassessment are as follows:

<table>
<thead>
<tr>
<th>Steps of the Reassessment</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Repeat the primary assessment.</td>
</tr>
<tr>
<td>2. Reassess and record vital signs.</td>
</tr>
<tr>
<td>3. Repeat the secondary assessment for other complaints, injuries, or a change in the chief complaint.</td>
</tr>
<tr>
<td>4. Check interventions.</td>
</tr>
<tr>
<td>5. Note trends in the patient’s condition.</td>
</tr>
</tbody>
</table>

Repeat and record the assessment findings—particularly the components of the primary assessment and the vital signs—at least every 5 minutes in the unstable patient with critical injuries and every 15 minutes in a stable patient.

**FIGURE 13-39** Steps of the reassessment.
REPEAT THE PRIMARY ASSESSMENT

Since the main objective of the primary assessment was to identify and manage life-threatening injuries, repetition of the primary assessment is also a key component of the reassessment. It is necessary to assess the same parameters that were initially assessed.

Reassess Mental Status

If the patient continues to talk to you throughout the entire call, reassess for any change in the speech pattern and appropriateness of his responses. A patient with a head injury may continue to talk to you, but his speech pattern may become garbled and his responses inappropriate. This is a sign of continued bleeding or swelling within the skull. Also assess the patient’s ability to obey commands appropriately. Repeat the Glasgow Coma Scale and obtain another score and compare it to the others.

If the patient is not alert or loses alertness, reassess the response based on the AVPU mnemonic. Record any change in the patient’s mental status, whether it is improved or worsened.

Reassess the Airway

If the patient is talking to you and in no distress, assume the airway is patent. In the unresponsive patient, open the mouth and look inside for any evidence of blood, secretions, or vomitus. Suction the mouth, if necessary. Listen for snoring sounds, gurgling, or stridor. Reassess the position of the nasopharyngeal or oropharyngeal airway if one has been inserted. Check to make sure either airway is not clogged with secretions, blood, or vomitus. If the patient is being ventilated, ask the EMT who is ventilating if any unusual resistance is felt. This may indicate an airway obstruction.

If the patient’s condition improves and he can no longer tolerate an airway adjunct and begins to gag, remove it. Have suction available and position the patient on his side, if possible, before removing the airway. Loss of a gag or cough reflex, on the other hand, may require insertion of an airway.

Reassess Breathing

Look, listen, and feel for adequate breathing. If the breathing is determined to be inadequate because of poor quality or rate, begin positive pressure ventilation with supplemental oxygen. If the patient is already being ventilated, reassess effectiveness of the ventilation by looking at the rise and fall of the chest and watching for improvement in the patient’s color and mental status. Ask the EMT who is ventilating if any unusual resistance is felt when squeezing the bag. If so, reevaluate the airway, the chest, the device being used for ventilation, the seal of the face mask, or the manner in which ventilation is being provided.

Reassess Oxygenation

Apply oxygen to any patient who exhibits any signs or symptoms of hypoxia, hypoxemia, respiratory distress, poor perfusion, or heart failure, or complains of dyspnea; or has a decrease in the SpO2 reading to less than 94%. The pulse oximeter should be used to monitor the effectiveness of oxygenation of the patient.

Reassess Circulation

Reassess Pulse

Reassess and record the patient’s pulse rate and quality. An increasing rate with poor quality may be a sign of continued bleeding. A decreasing pulse with poor quality may indicate a head injury or severe hypoxia (oxygen starvation). An increasing pulse in a patient who initially had a low rate may indicate an improvement in breathing and oxygenation. If a patient initially had an elevated pulse associated with bleeding, a decrease may indicate a reduction in the bleeding and an improvement in the patient’s condition. Evaluate the pulse rate in relationship to the initial findings and the injuries or medical condition.

Reassess Bleeding

Check the site of any major bleeding for blood seeping through the dressing and bandage, indicating the need to recontrol bleeding through direct pressure. If the bleeding is severe and cannot be controlled with direct pressure, apply a tourniquet. If you detect any signs of increasing or continued blood loss, such as a decrease in perfusion or elevated pulse with poor quality, conduct a rapid assessment to detect the site of any external blood loss that you can control. Continue to treat for shock.
Reassess Skin
Look for skin color changes. Feel for changes in skin temperature and condition. Reassess capillary refill. Improvements in oxygenation typically improve the color of the skin. Likewise, poor oxygenation from airway or breathing compromise will cause the skin to become cyanotic or blue-gray. As a patient continues to lose blood, the skin becomes more pale, cool, and clammy. Capillary refill may be delayed. Continue to treat for shock.

Return of normal skin color, temperature, and condition are obvious indications of improvement.

Reestablish Patient Priorities
If reassessment is undertaken at the scene and deterioration of the patient’s condition is noted, it may be necessary to reconsider your emergency care and transport decision. If the patient becomes a priority patient because of the injuries or conditions found, begin prompt transport and continue to provide emergency care while en route to the hospital. If the patient’s condition deteriorates, reassess and adjust interventions as needed.

COMPLETE THE REASSESSMENT

Reassess and Record Vital Signs
During the reassessment, reassess the breathing rate and quality, pulse rate and quality, perfusion status, pupils, blood pressure, and SpO₂. Record the vital signs and the time that they were taken.

Repeat Components of the Secondary Assessment for Other Complaints
If the patient begins to complain of a symptom that was not initially identified or a change in the original symptom, complete the relevant components of the secondary assessment related to the area of the complaint and other relevant body systems. Obtain additional history information, if necessary. The patient may have been initially unresponsive and unable to identify any complaints. However, as a result of effective care and improvement in his condition, the patient begins to complain of symptoms of injury or medical illness. Repeat components of the physical assessment as necessary to focus on those areas or symptoms. For example, during the reassessment a patient begins to complain of abdominal pain. You must reinspect and palpate the abdomen, looking for any additional signs of injury or abnormality.

Check Interventions
Determine if your emergency care is adequate and your interventions are effective for the patient’s condition. Ensure adequacy of oxygen delivery, positive pressure ventilation, bleeding control, CPR or AED, and immobilization.

Ask yourself the following questions when considering adequacy of intervention:

• Have the patient’s vital signs improved, or deteriorated?
• Is the patient’s airway still patent?
• Is the oxygen device and liter flow adequate? Is oxygen connected and flowing to the bag-valve-mask device?
• Has the patient’s SpO₂ improved with oxygen or should I consider positive pressure ventilation?
• Is the patient’s chest rising and falling adequately with the ventilations?
• Are the chest compressions producing pulses? Is the rate and depth of compression adequate?
• Has a cardiac arrest patient whose heartbeat has been restored lapsed into arrest again?
• Is the AED indicating that a shock is needed (or not needed)?
• Is the pressure dressing adequately controlling the bleeding? Has the bleeding stopped or do I need to proceed to the next step in bleeding control?
• Is the patient’s spine completely immobilized?
• Are bone or joint injuries adequately immobilized?

If an intervention is not effective, it may be necessary to reassess the patient’s condition, look for signs of other injuries or illness, check the equipment, ensure that the equipment is being used properly, and/or select alternative methods for emergency care.

Assessment, intervention, and reassessment of the patient is the key to all emergency care provided in the prehospital environment.

Note Trends in Patient Condition
The changes for the better or worse in the patient’s condition will be the basis for interventions or changes in intervention and reassessment that you will perform en route to the hospital. It is also important to document and report to the staff of the receiving facility any changes in the patient’s condition. For both the EMTs and the hospital staff, it is not only the patient’s condition, but the trends in the patient’s condition, indicating improvement or deterioration, that are important.
Log Rolling from a Prone to a Supine Position When Spinal Injury Is Suspected

**13-1A** A rescuer at the patient’s head establishes and maintains manual in-line spinal stabilization. A backboard is placed alongside the patient, and two other rescuers kneel on it. One grasps the patient’s shoulder and hip. The other grasps the patient’s thigh and ankle.

**13-1B** On the command of the rescuer at the head, the patient is rolled up against the thighs of the kneeling rescuers. The rescuer who is grasping the patient’s thigh and ankle makes sure that the legs are slightly raised off the floor to keep them aligned with the spine as the patient is turned.

**13-1C** The patient is then rolled into the supine position on the backboard. In-line spinal stabilization is maintained by the rescuer at the head.

Assessing Capillary Refill in Children and Infants

**13-2A** To assess capillary refill, press your thumb down on the child’s kneecap for several seconds.

**13-2B** Release your thumb and observe the whitened (blanched) area where you had been pressing. Count the number of seconds it takes for the color to return to normal. Normal color should return to the area in 2 seconds or less. If it takes longer, capillary refill is said to be delayed. This is only one sign of inadequate circulation. You must assess for other signs of poor perfusion.
**EMT SKILLS 13-3**

### The Secondary Assessment: Anatomical Approach

- **13-3A** Inspect the head for signs of trauma. Carefully palpate the skull for abnormalities.

- **13-3B** Inspect and palpate the ear. Note any leakage of blood or fluid.

- **13-3C** Inspect behind the ears for any injury or discoloration.

- **13-3D** Inspect and palpate the face. Note any deformity, instability, burns, or swelling.

- **13-3E** Assess both pupils for equality of size and reactivity to light. Inspect the color of the sclerae.

- **13-3F** Check eye movement by having the patient follow your finger. Note any gazes in one direction or jerky eye movements.
13-3G Inspect the conjunctiva by pulling the lower eyelid down.

13-3H Inspect and palpate the nose for any signs of trauma, burns, bleeding, or fluid leakage.

13-3I Inspect the inside of the mouth for signs of trauma, burns, and discoloration. Note the color of the mucous membranes. Smell the breath for any unusual odor.

13-3J Assess the neck for jugular vein distention, tracheal deviation, accessory muscle use, and subcutaneous emphysema.

13-3K Inspect and palpate the entire chest. Check for symmetry of chest wall movement. Palpate the sternum, clavicles, and shoulders.

13-3L Auscultate breath sounds, comparing one side to the other.

continued
continued

■ **13-3M** Inspect and palpate each quadrant of the abdomen. Note any guarding, tenderness, or rigidity.

■ **13-3N** Assess the stability of the pelvis in a patient who is unresponsive or who has no noted pain in that area.

■ **13-3O** Inspect and palpate each lower extremity. Look for signs of wounds, bleeding, deformity, swelling, and discoloration.

■ **13-3P** Assess distal pulses in each lower extremity. Also note skin color, temperature, and condition.

■ **13-3Q** Check motor response of both lower extremities by having the patient push both feet against your hands. Compare and note the equality of strength.

■ **13-3R** Assess sensation by first lightly touching a toe and asking the patient to identify which toe you are touching and then pinching the foot to check for pain response. If the patient is unresponsive, pinch the foot and note the patient’s reaction.
Inspect and palpate each upper extremity.

Assess the radial pulse on each upper extremity. Note skin color, temperature, and condition.

Assess motor function by having the patient grip the fingers of both your hands simultaneously. Note equality of strength. Assess sensory function by asking the patient to identify which finger you are touching. Then pinch the hand and ask the patient to identify the hand where he feels pain. If the patient is unresponsive, pinch the hand and note the patient’s reaction.

Common Signs of Trauma

- Deformities. © Edward T. Dickinson, MD
- Contusions. © Edward T. Dickinson, MD
continued

13-4C  Abrasions. (© Pat Songer)

13-4D  Punctures/penetrations. (© Charles M. Stewart, MD EMDM MPH)

13-4E  Burns. (© Edward T. Dickinson, MD)

13-4F  Tenderness.

13-4G  Lacerations. (© Edward T. Dickinson, MD)

13-4H  Swelling. (© Edward T. Dickinson, MD)
Inspect and palpate the scalp and skull. Inspect and palpate the face, including ears, pupils, nose, and mouth. Pay particular attention to injuries that could block the airway with blood, bone, teeth, or tissue.

Inspect the neck for tracheal deviation, tracheal tugging, jugular vein distention, subcutaneous emphysema, and large lacerations or punctures.

Palpate both the anterior and posterior aspects of the neck. Note posterior muscle spasms that may indicate injury to the cervical spine.

Apply a cervical spinal immobilization collar (CSIC) if not already done during or after the primary assessment.

Expose the chest. Inspect and palpate for open wounds, flail segments, muscle retractions, and asymmetrical chest movement.

continued
Inspect the pelvis for evidence of trauma. If the patient complains of pain or there is obvious deformity, do not palpate.

Inspect and palpate each lower extremity.

Assess pedal pulses.

Assess motor and sensory function in each foot.

Perform a quick four-point auscultation of the chest to listen for the presence and equality of breath sounds.

Inspect the abdomen for any evidence of trauma or distention. Palpate for tenderness and rigidity.
Assess and palpate each upper extremity.

Assess distal pulse, motor, and sensory function in each upper extremity.

With in-line spinal stabilization maintained, roll the patient to inspect the posterior body.

inspect and palpate the head.

Inspect the neck for jugular vein distention, excessive neck muscle use when the patient inhales, medical identification tag, or tracheostomy tube.
continued

13-6C A medical identification tag, usually worn around the neck or the wrist, will provide medical information about the patient.

13-6D Inspect the chest for adequate rise and fall, muscle retraction, and symmetry. Auscultate the breath sounds.

13-6E Inspect the abdomen for scars, discoloration, or distention. Palpate for tenderness, rigidity, distention, and pulsating masses.

13-6F Assess the upper and lower extremities.

13-6G Assess pulses in all four extremities.

13-6H Assess motor and sensory function in all four extremities.

Conclude the rapid secondary assessment for the medical patient by inspecting and palpating the posterior body.
The Reassessment

■ 13-7A Reassure the patient as you begin to repeat the primary assessment.

■ 13-7B Reassess vital signs.

■ 13-7C Repeat appropriate elements of the physical exam.

■ 13-7D Check and adjust interventions as necessary.

■ 13-7E Record trends in the patient’s condition.
SUMMARY

The patient assessment is one of the most important functions you will perform as an EMT. The assessment determines your emergency care of the patient. If the assessment is not performed accurately or thoroughly, your emergency care may not be adequate, because injuries and conditions may have been overlooked.

Every patient assessment begins with the scene size-up. This was covered in detail in Chapter 12. The scene characteristics may provide clues as to whether the patient is injured or ill. In addition, it may provide information on the mechanism of injury (how the patient was injured) that may lead you to a higher index of suspicion for certain injuries. The scene size-up will also determine the approach to your secondary assessment, whether it will be for a trauma or a medical patient.

The actual physical examination begins with the primary assessment, which is performed to identify and manage immediate life threats to the airway, breathing, oxygenation, and circulation. If a life threat is found, you must immediately intervene to provide the necessary emergency care. A primary assessment will be performed on every patient, regardless of his complaint, his mechanism of injury (MOI) or nature of the illness (NOI), or his mental status.

Following the primary assessment, you must perform a secondary assessment. A trauma assessment is performed on any patient with an MOI. There are two types of trauma assessment: the rapid secondary assessment and the modified secondary assessment. If the patient is unresponsive or has an altered mental status, has multiple injuries, has suffered a significant MOI, or is unstable, you will proceed with the rapid secondary assessment. This is a rapid head-to-toe assessment that is done to identify and manage all other life threats (other than those already managed during the primary assessment). You are assessing for critical injuries that require rapid intervention or rapid transport, or both. If the patient has only an isolated injury and there is no evidence of an altered mental status, no abnormal finding in the primary assessment, and no suspicion of multiple injuries, you will conduct a modified secondary assessment, a physical exam that focuses on the specific injury or body systems. If there is any doubt as to which assessment to perform (the rapid head-to-toe secondary assessment or the modified secondary assessment on the specific injury), always err on the side of benefiting the patient and do a rapid secondary assessment.

In the medical patient, more information can be gathered from the history than from the physical exam. Therefore, if the medical patient is alert, responsive, and oriented, you will first conduct a history, then a secondary assessment of anatomical areas and body systems associated with the chief complaint, and finally an assessment of baseline vital signs. However, if the medical patient is not alert, is disoriented, is responding to verbal or painful stimuli, or is unresponsive, you will first conduct a rapid secondary assessment (head-to-toe physical exam), then the assessment of baseline vital signs, and finally a history (which you will gather as best you can from family or other witnesses). The rapid secondary assessment for the medical patient is almost identical to the rapid secondary assessment for the trauma patient.

The last phase of the assessment is the reassessment. A reassessment is performed every 5 minutes in the unstable patient and every 15 minutes in the stable patient. It is conducted to reassess the primary assessment, baseline vital signs, any other complaints, and the interventions that have already been done. It also allows you to monitor trends—any improvement or deterioration—in the patient’s condition.

You will perform the following three parts of the assessment on every patient you encounter in the prehospital setting: a primary assessment, a secondary assessment, and a reassessment.

The assessment is your tool to gather critical information about the patient so you can provide efficient and effective emergency care.

Case Study Follow-up

During your shift as an EMT, you are called to two different kinds of cases. The first call is to a trauma patient. The second is to a patient who is suffering from a medical problem.

CALL ONE—A TRAUMA PATIENT

Scene Size-up

You have been dispatched to an unresponsive patient with an unknown problem. Upon arrival, you see an adult male supine at the bottom of a two-story fire-escape ladder. A police officer approaches the ambulance and tells you that they have been called for a reported domestic incident and gunshots. The officer motions you to park a safe distance away until the scene is secured. Moments later you see police leading a suspect from the building. The officer motions you forward and tells you the scene is safe. Anticipating that the patient may be bleeding, you already have on gloves, mask, and eyewear with side shields as you jump from the ambulance and approach the patient.

Primary Assessment

As you approach the patient, you notice that the shirt front and left pants leg are soaked in blood, the skin is extremely pale, and the right lower leg is severely

continued
deformed. This is obviously a trauma patient with a significant mechanism of injury—a probable fall from the fire escape and a possible gunshot wound.

Your partner immediately establishes in-line stabilization of the head and neck and performs a jaw thrust to open the airway. The patient does not respond to verbal commands; however, he moans and makes a facial grimace as you pinch the trapezius muscle.

You assess the breathing status and determine that the patient’s chest is barely rising and falling and only minimal air movement can be felt or heard. You immediately instruct your partner to insert an oropharyngeal airway and begin bag-valve-mask ventilation at a rate of 10/minute with supplemental oxygen while maintaining in-line stabilization. A radial pulse is not palpable and the carotid pulse is extremely weak, fast, and thready. The skin is pale, cool, and clammy.

As you continue with your assessment, you quickly cut the shirt off and find a gunshot wound to the left anterior chest. You immediately place your gloved hand over the wound. You then tape the plastic package from an oxygen mask over the wound on three sides and continue to scan the anterior and lateral aspects of the chest for any other wounds.

Next, you expose the area around the left thigh and find a wound with dark red bleeding at a steady flow. You apply direct pressure to control the bleeding and then immediately apply a pressure dressing.

You indicate to your partner that this is going to be a rapid patient transport.

Secondary Assessment

Now that immediate life threats are under control, you begin the rapid secondary assessment. You quickly assess the head and neck and apply a cervical spinal immobilization collar. Your partner continues in-line stabilization.

As you continue with your assessment, you find decreased breath sounds on the left side of the chest. You find no abnormalities in the abdominal or pelvic region, but the right lower extremity is swollen and deformed and the patient moans when you palpate the angulated area. With assistance from police First Responders, spinal stabilization is maintained as the patient is log rolled and the posterior thorax and lumbar region and buttocks are exposed. No additional injuries are revealed.

While the patient is still on his side, a police First Responder slides the backboard next to the patient and the patient is rolled onto it and secured with straps. A head immobilization device is applied. The right lower extremity is also carefully secured to the board for stabilization.

The blood pressure is measured at a low 70/50 mmHg; skin remains pale, cool, and clammy; pupils are normal in size, equal, and sluggishly to respond to light; the heart rate is rapid at 136 per minute; and the spontaneous respiratory rate is only 6 per minute. You continue positive pressure ventilation with supplemental oxygen at a rate of 10 per minute.

No one at the scene knows the patient, so the only portion of the history you are able to gather is information about events leading to the injury. A neighbor reports hearing gunshots, seeing the patient stagger out onto the second-story fire escape clutching his chest, then watching in horror as the patient pitched over the railing and fell to the pavement.

The patient is promptly loaded into the ambulance for transport with lights and siren.

En route to the hospital, you apply a vacuum splint to the right lower leg for better immobilization.

You apply a sterile dressing and bandage to a small laceration at the left temporal region of the patient’s head.

Reassessment

Because this is a patient with critical injuries, you continuously reassess the mental status, airway, breathing, oxygenation, and circulation, and you take and record vital signs every 5 minutes while en route to the emergency department. You reassess the patient’s injuries and check the effectiveness of interventions, making sure that positive pressure ventilation is adequate, the dressing on the chest wound is permitting escape of air on the unsecured side, the bleeding at the chest and thigh is under control, and the immobilization to the backboard and splints is secure. You radio the hospital emergency department to report patient information and to alert them to your estimated time of arrival. No change in the patient’s condition has occurred and you arrive at the hospital without further incident.

You give the hospital staff your oral report on the patient, complete the written documentation, and prepare the ambulance for the next call.

CALL TWO—A MEDICAL PATIENT

Scene Size-up

Shortly after the call to the man injured in the domestic dispute, you are again dispatched to a patient with an unknown problem. This time, you arrive at a well-kept home in a quiet neighborhood and are met by a middle-aged woman who says she called EMS for her mother, who cannot catch her breath. The woman, Mrs. Conlon, leads you into the house. As you enter the living room, you see an elderly woman sitting up in a chair and an oxygen tank in the corner. You conclude that your patient likely is suffering from a medical problem rather than trauma.

Primary Assessment

Mrs. Conlon introduces you to her mother, Mrs. Ortega, and tells you that her mother is 72 years old. Mrs. Ortega is sitting up in a chair, leaning forward, with her hand on her chest. She says, “I’m glad—you came. I feel like—I can’t...”
breathe." Her remarks assure you that her mental status is alert and her airway is open. You observe that she is breathing in fast, short puffs, but with adequate rise and fall of the chest. Your partner applies the pulse oximeter and obtains a reading of 89%. You apply a nasal cannula at 2 lpm, explaining that this will help relieve her distress. Because she has a home supply of oxygen that she has occasionally used, she understands and welcomes the oxygen therapy. You are able to palpate a somewhat rapid radial pulse, and you note that her skin is warm, pink, and dry.

**Secondary Assessment**

You sit down on a chair next to Mrs. Ortega and begin to take the history, starting with an elaboration of the chief complaint. She is not experiencing pain, so most of the OPQRST questions do not apply, but she does tell you that the onset of her symptoms was gradual over this morning and afternoon and that she has been suffering from the breathing difficulty for several hours. You determine that she chronically has a difficult time breathing, but this episode was slightly worse than usual—a 5 on a scale of 1 to 10. You continue with the assessment using the mnemonic as the foundation for asking questions. She has no allergies that she knows of. The medications she takes, including oxygen, are related to her history of emphysema, a serious lung disease. Her last oral intake was lunch at around noon. There were no unusual events leading to the onset of the symptom.

Meanwhile, your partner has been taking and recording Mrs. Ortega’s baseline vital signs. Her respirations are puffy, somewhat labored, and at a rate of 28 per minute with adequate chest rise. Her pulse is rapid at 100 per minute and irregular. Her skin color, temperature, and condition remain normal. Pupils are normal, equal, and reactive. Her blood pressure is 120/90 mmHg. The pulse oximeter reading has improved only slightly to 90% while on the nasal cannula at 2 lpm so you increase the flow to 3 lpm and continue to monitor the SpO₂ reading.

The physical exam you conduct is focused on Mrs. Ortega’s complaint and related body systems. You assess her pupils and find that they are midsize and reactive. Her oral mucosa and conjunctiva are slightly cyanotic. Her neck veins are flat. You quickly inspect the chest by lifting her shirt to look for any potential evidence of trauma. You auscultate her chest with your stethoscope and detect wheezing noises that, in fact, you can hear even without the stethoscope. The breathing sounds are present and equal on both sides. Her abdomen is nontender and no distention is noted. You inspect the lower extremities for redness and swelling, especially to one calf. You quickly palpate trying to elicit a tenderness response. You ask Mrs. Ortega to “Point your toes back toward your head” checking for tenderness in either calf region. You then ask her to “Point your toes” again checking for any tenderness. You inspect the ankles and feet for edema.

You place Mrs. Ortega on the wheeled stretcher and transfer her to the ambulance. You raise the head of the stretcher so that she can ride to the hospital in a sitting position, which she finds is more comfortable and helps her to breathe.

**Reassessment**

You perform a reassessment by reassessing her mental status, airway, breathing, oxygenation, and circulation, and reassessing and recording her vital signs. You repeat an assessment focused on her breathing problem by using your stethoscope to auscultate her chest and reconfirm that breath sounds are present and equal with wheezing sounds on both sides. You assess the SpO₂ reading to ensure the nasal cannula at 3 lpm is keeping the SpO₂ at or above 94%. Because Mrs. Ortega is a stable patient, you repeat the reassessment every 15 minutes en route. You radio the hospital emergency department with patient information and your estimated time of arrival.

You arrive at the hospital with no further incident, give your oral report to the receiving staff, complete the transfer of care, finish theprehospital care report, and prepare the ambulance for the next call.

**IN REVIEW**

1. Briefly state the purposes of patient assessment by the EMT.
2. List the main components of patient assessment.
3. List the three steps of the scene size-up.
4. List the components of the primary assessment.
5. Contrast the order of the three steps of the secondary assessment for a responsive medical patient with the order of the steps for an unresponsive medical patient or trauma patient. Explain why the order of the steps differs.
6. Describe the kinds of patients for whom the physical exam should be a rapid head-to-toe assessment (rapid secondary assessment). Describe the kinds of patients for whom the physical exam should be focused on a specific site or area of complaint (modified secondary assessment).
7. Name the five categories of measurements that are included in the vital signs.
8. Name the categories of information sought during history taking that the letters in OPQRST and SAMPLE represent.
9. State how often, at a minimum, during the reassessment, the components of the primary assessment and the vital signs should be reassessed for the following: (a) a critical or unstable patient and (b) a stable patient.
CRITICAL THINKING

SCENARIO 1
You are called to the scene for a 23-year-old male who fell approximately 20 feet from a balcony at a concert. The patient is not alert as you approach him. He has blood coming from his mouth and ears. His left arm is angulated and obviously fractured. A bystander states he was talking and moaning right after he fell, but now he won’t respond.

1. What would be your first immediate action when you arrive at the patient?
2. What assessment should you conduct first?
3. What are the components of that assessment and in what order would you perform them?
4. What life threats are you assessing for and how would you manage them?
5. What injuries should you suspect in this patient?
6. What baseline vital signs would you assess?
7. Would you perform a rapid secondary assessment or a modified secondary assessment?
8. What does the change in his mental status indicate?
9. When would you transport?
10. How would you prepare the patient for transport?
11. What would you do while en route to the medical facility?

SCENARIO 2
You are called to the scene for a 78-year-old female complaining of shortness of breath. As you arrive on the scene, her daughter lets you into the house and directs you to her mother. The patient is lying supine on the couch and appears to be extremely pale and cyanotic. You hear snoring sounds when she breathes. The daughter states that her mother has a heart condition and hasn’t been feeling well for 2 days. She thought her mother was napping on the couch, but when she went to wake her, her mother did not respond.

1. Do you suspect she is a trauma or medical patient?
2. What would be your first immediate action when you arrive at the patient?
3. What assessment should you conduct first?
4. What are the components of that assessment and in what order would you perform them?
5. What life threats are you assessing for and how would you manage them?
6. Would you collect a history first or do a medical assessment?
7. Would you perform a rapid secondary assessment or a modified secondary assessment?
8. How would you collect a history?
9. What does the mental status possibly indicate?
10. What would you expect the SpO₂ reading to be?
11. When would you transport?
12. How would you prepare the patient for transport?
13. What would you do while en route to the medical facility?
PART 7  Pharmacology

CHAPTER 14  Pharmacology Medication and Administration

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD**  •  Pharmacology (Content Areas: Principles of Pharmacology; Medication Administration; Emergency Medications)

**COMPETENCY**  •  Applies fundamental knowledge of the medications that the EMT may assist/administer to a patient during an emergency.

**OBJECTIVES**  •  After reading this chapter, you should be able to:

14-1. Define key terms introduced in this chapter.
14-2. Describe the roles and responsibilities associated with administering and assisting patients with administration of medications.
14-3. Differentiate between administration of medication and assisting a patient in taking his own medications.
14-4. List the medications in the EMT’s scope of practice.
14-5. Differentiate between a drug’s chemical, official, generic, and trade names.
14-6. Demonstrate the proper administration of drugs by each of the following routes:
   a. Sublingual
   b. Oral
   c. Inhalation
   d. Intramuscular (epinephrine auto-injector only)
14-7. Differentiate between the following medication forms:
   a. Tablet
   b. Liquid for injection
   c. Gel
   d. Suspension
   e. Fine powder for inhalation
   f. Gas
   g. Liquid for spray or aerosolization
14-8. Explain the roles of off-line and on-line medical direction with regard to medication administration.
14-9. Adhere to the following key steps of medication administration:
   a. Obtain an order.
   b. Verify on-line orders.
   c. Select the proper medication.
   d. Verify the patient’s prescription.
   e. Check the expiration date.
   f. Check for impurities and discoloration.
   g. Verify the form, route, and dose.
   h. Ensure that the “five rights” of medication administration are followed.
14-10. Document required information regarding medication administration.
14-11. Describe the reassessment of a patient after you have administered or assisted the patient in taking a medication.

**KEY TERMS**  •  Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

INTRODUCTION

As an EMT you will be responsible for administering or assisting the patient with the administration of certain medications. Unlike a mathematician, you cannot erase your mistakes and start over. Once a medication has been administered, you cannot extract it or prevent its effects. Improper use of a medication may have dangerous consequences for the patient. Therefore, it is vital that you be completely familiar with the medications and the proper procedures for administration.

Only certain patients who have specific chief complaints or signs and symptoms will require medication. Either the medication will be carried on the EMS unit or it will be prescribed to the patient. Regardless of the source of the medication, you must attain medical direction’s permission, whether as an off-line standing order or it will be prescribed to the patient. Regardless of the source of the medication, you must attain medical direction’s permission, whether as an off-line standing order or as an on-line order you receive by direct communication with medical direction, before you administer or assist the patient with administering a medication.

ADMINISTERING MEDICATIONS

A medication is generally defined as a drug or other substance that is used as a remedy for illness. A drug is a chemical substance that is used to treat or prevent a disease or condition. The terms drug and medication are often used interchangeably by EMTs. The study of drugs is referred to as pharmacology.

The EMT must take seriously the responsibility of administering medications. Medications have specific physiological effects on the cells, organs, or body systems. When the correct dose is administered appropriately, the patient’s condition may improve significantly and uncomfortable symptoms may be relieved. If administered inappropriately, some drugs can cause serious side effects and deterioration in the patient’s condition.

As an EMT, you will be administering medications under the direct order of a licensed physician. Without this order, you cannot administer any type of medication. Also, the EMT is only able to administer the medications identified in the local protocol, which may include all or some of the medications covered in this chapter.

Remember that you may not administer or assist with administration of any medication other than the medications that are identified in local protocols. For example, if you arrive on the scene and find a patient experiencing excruciating pain associated with a dislocated shoulder, and you find the patient’s prescription of Percodan at his side, it would be inappropriate for you to suggest, administer, or assist with the administration of the medication. Even though Percodan is a pain reliever, and it might seem to “make sense” to use it to make the patient more comfortable, it is not an acceptable medication to be administered by an EMT. An EMT can only administer medications within his scope of practice.

Some systems clearly distinguish between the EMT administering and assisting the patient with the administration of a medication. Administration of a medication implies that the EMT will actually take all of the steps necessary to give the patient the medication via an oral, injection, or inhalation route. The patient simply takes the direction from the EMT while receiving the medication. If the orders clearly state that the EMT will assist with the administration of the medication, the EMT will prepare the medication and then hand it over to the patient who will then proceed with taking the medication. As an example, if the orders state that the EMT can administer aspirin to the patient, the EMT will obtain cautiously. Upon entry, you find an elderly man sitting on the hallway floor against the wall. You immediately turn on the hall light. A scan of the scene does not reveal any potential hazards. The patient is clutching his chest, complaining of severe, crushing pain.

How would you proceed to assess and care for this patient—including the administration of medication?

During this chapter, you will learn about assessment and emergency care for a patient whose condition may require administration of a medication. Later, we will return to the case and apply the procedures learned.
the aspirin, instruct the patient to chew the aspirin, and place it in his mouth. If the orders only allow the EMT to assist with administration of the aspirin, the EMT will obtain the aspirin, instruct the patient to chew the aspirin, hand the patient an aspirin tablet, and have the patient place it into his mouth.

**MEDICATIONS COMMONLY ADMINISTERED BY THE EMT**

Medications administered by the EMT are either carried on the EMS unit or are prescribed for the patient. The prescription medications may be found on the patient or at the scene. General steps for properly administering all of the medications mentioned in this section are detailed at the end of this chapter.

### Medications Carried on the EMS Unit

The following medications may be carried on the EMS unit. Even though the EMT controls the administration of these medications and they are ready at hand on the ambulance, an off-line or on-line order from medical direction is still necessary.

### Oxygen

Oxygen is an odorless, tasteless, colorless gas that is found in the ambient atmosphere at a concentration of approximately 21 percent. When it is used for medical purposes, it is administered as a 100 percent compressed gas concentration. Oxygen is indicated in any patient who you suspect is hypoxic, hypoxemic, or complains of dyspnea or has evidence of respiratory distress; has signs of shock, poor perfusion, or heart failure; or has an SpO2 reading <94% or an unknown oxygen saturation reading and appropriate medical condition that requires oxygen. By increasing the oxygen concentration breathed in by the patient, you are attempting to put a higher concentration of oxygen into the alveoli of the lungs. By doing so, you will increase the amount of oxygen crossing over from the alveoli and into the pulmonary capillary. This will allow more oxygen molecules to be available to attach to the hemoglobin on the surface of the red blood cell. By increasing the number of oxygen molecules attached to the hemoglobin, more oxygen will circulate in the blood and be delivered to the hypoxic or potentially hypoxic cells. Oxygen was covered in detail in Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

### Oral Glucose

Glucose is a simple sugar that is found in the blood. It is the primary energy source for the body cells. Most cells throughout the body are capable of using other energy sources if they can’t get enough glucose. Brain cells, however, can use only glucose for energy. When the brain cells do not get an adequate amount of glucose, they begin to function improperly, and the patient will exhibit an altered mental status. The signs and symptoms of a low blood glucose level will appear very rapidly. If the level drops too low for a long period of time, the brain cells can actually die.

Oral glucose is administered to the patient with a history of diabetes who is suspected of having a low blood glucose level. The oral glucose is absorbed in the mouth and through the intestines and eventually into the blood, where it will raise the blood glucose level, making more glucose available to the starving brain cells. The brain cells will once again begin to function normally. This will be seen as an improvement in the mental status. Oral glucose will be covered in detail in Chapter 20, “Acute Diabetic Emergencies.”

### Activated Charcoal

Activated charcoal is a fine black powder that is designed to adsorb, or bind, an ingested poison to the charcoal. Once this occurs, the poison will be carried by the charcoal through the digestive tract and then eliminated in a bowel movement. The efficacy of activated charcoal has been questioned and it may have harmful effects if aspirated. Activated charcoal has been removed from many protocols. Activated charcoal will be covered in detail in Chapter 22, “Toxicologic Emergencies.”

### Aspirin

Aspirin is administered to a patient who is having chest discomfort or pain that is related to the lack of oxygen getting to the heart. The administration of aspirin may keep the vessels that deliver blood to the heart (the coronary arteries) from completely closing shut. Aspirin will be covered in detail in Chapter 17, “Cardiovascular Emergencies.”

### PATHOPHYSIOLOGY PEARLS

**Aspirin**

Aspirin keeps the platelets in the blood from sticking together. This prevents the platelets from forming a clot and completely closing off a coronary blood vessel in the heart, thereby maintaining some blood flow to that portion of the heart muscle.

### Medications Prescribed for the Patient

Some of the medications that the EMT may administer or assist the patient with administering are not carried on the EMS unit. Instead, they are medications prescribed
Inhaled Bronchodilator

Medications that cause the bronchioles to dilate are delivered via two different routes: metered-dose inhaler or small-volume nebulizer.

**Metered-Dose Inhaler.** A metered-dose inhaler (MDI) is used by a patient who has some type of respiratory disease. Most often, you will find MDIs prescribed to patients with a history of asthma, emphysema, and chronic bronchitis. These patients will have episodes of bronchoconstriction in which the bronchioles in the respiratory tract will constrict, increasing the resistance to air flowing into the lungs and down into the alveoli. The patient will experience shortness of breath and signs and symptoms of respiratory difficulty from the increased effort to breathe and from the decreased flow of oxygen to the alveoli. An MDI that you are able to administer or assist the patient with is one that contains a beta2-agonist drug. A beta2-agonist drug will cause the bronchioles to dilate (open; increase in diameter), decreasing the airway resistance and increasing the airflow through the respiratory tract and into the alveoli. Metered-dose inhaler medications (albuterol, levalbuterol) will be covered in detail in Chapter 16, “Respiratory Emergencies.” A non-beta2-agonist medication administered via a metered-dose inhaler can also be delivered through a small-volume nebulizer (SVN). The indications, actions, side effects, and contraindications of the medication are the same; only the route of delivery is different.

To nebulize a medication, you place it into a specialized chamber and pass oxygen or compressed air through it to create a fine vapor. The fine vapor is expelled through a T-tube and into a mouthpiece or mask. The patient then inhales the vapor through the mouthpiece or mask over a period of several minutes and until the medication is completely gone from the chamber. Note that an MDI is designed to deliver the medication with one inhalation, whereas the nebulizer is designed to create a continuous flow of vapor that contains the medication. With each inhalation, the patient breathes in the beta2-specific medication, which is then topically deposited in the bronchioles and at the site of bronchoconstriction.

Some EMTs carry nebulizer equipment and beta2-specific drugs for nebulization on the ambulance. Others are allowed to administer or assist the patient with administration of the beta2 by using the patient’s home nebulizer.

**Nitroglycerin**

Nitroglycerin is a medication that is used to treat cardiac patients with diseases of the coronary arteries that deliver blood to the heart. The medication is commonly referred to as “nitro.” Nitroglycerin is a vasodilator; that is, it dilates the blood vessels in the body. By doing so, it reduces the workload of the heart, thereby decreasing the demand for oxygen by the heart muscle. In addition, it dilates the coronary arteries themselves, which increases the supply of oxygenated blood to the heart muscle.

Because it is a vasodilator, the major side effect of the drug is hypotension (low blood pressure). It is extremely important to measure the blood pressure prior to and after administration of nitroglycerin. Nitroglycerin must not be administered (that is, it is contraindicated) to patients taking medications for erectile dysfunction, which themselves lower blood pressure. In particular, patients who have taken tadalafil (Cialis), vardenafil (Levitra), or sildenafil (Viagra) within the last 48 hours should never be given nitroglycerin. The combined blood-pressure-lowering effects of the nitroglycerin and the erectile dysfunction medication may cause serious drops in blood pressure and perfusion and can lead to death. Nitroglycerin will be covered in detail in Chapter 17, “Cardiovascular Emergencies.”

**Epinephrine**

Epinephrine is a drug used to treat patients suffering from severe allergic reactions known as anaphylaxis. An anaphylactic reaction usually occurs when the patient ingests, injects, inhales, or absorbs a substance that the body views as foreign. The body then reacts with a
misdirected and exaggerated immune response that can easily lead to death. The patient’s blood vessels dilate (vasodilation), decreasing the blood pressure and perfusion; the bronchioles constrict (bronchoconstriction), increasing the airway resistance and making it difficult to move air into the alveoli; and the capillaries leak fluid out (from increased capillary permeability), causing the blood volume to decrease. These all can produce serious signs and symptoms in the patient and lead to failure of the respiratory and cardiovascular systems.

Many patients with a history of anaphylactic reaction will carry an epinephrine auto-injector. This is a prefilled single-dose or multidose spring-loaded device that delivers a specific dose of epinephrine when activated. The epinephrine constricts the vessels, increasing the blood pressure; dilates the bronchioles, allowing the patient to move more air into the alveoli; and decreases capillary permeability, reducing the leakage of fluid. Epinephrine will be covered in detail in Chapter 21, “Anaphylactic Reactions.”

**ASSESSMENT TIPS**

Epinephrine stimulates four receptors: alpha\(_1\), alpha\(_2\), beta\(_1\), and beta\(_2\). These properties make up the sympathetic nervous system function. Following the administration of epinephrine, the patient may experience an increase in the heart rate due to the beta\(_1\) properties of the epinephrine.

### MEDICATION NAMES

A medication, or drug, can have up to four different names: chemical, generic, trade (brand), and official. These names are assigned during the development of the drug and are used interchangeably. The EMT must be most familiar with the generic and trade names. Table 14-1 lists generic and trade names and common uses for the medications the EMT may be allowed to administer or assist the patient with administering.

A description of the four drug names is as follows:

- **Chemical name.** The chemical name describes the drug’s chemical structure. It is usually the first name associated with the drug.

- **Generic name.** Also referred to as the nonproprietary name, the generic name still reflects the chemical characteristic of the drug, but in a shorter form than the full chemical name. It is the name assigned to the drug before it is officially listed and is independent of the manufacturer. The generic name is listed in the U.S. Pharmacopoeia, a publication listing all drugs officially approved by the U.S. Food and Drug Administration.

- **Trade name.** The trade name, also referred to as the brand name, is assigned when the drug is released for commercial distribution. The name is usually short and easy to recall, and may be based on

the chemical name or the type of problem it is used to treat. This is the name the manufacturer uses to market the drug.

- **Official name.** Drugs meeting the requirements of the U.S. Pharmacopoeia or National Formulary are given an official name. It is commonly the generic name followed by the initials U.S.P. or N.F.

An example of the four drug names for the common nitroglycerin tablet taken by many patients with chronic chest pain is as follows:

- **Chemical Name:** 1,2,3-propanetriol trinitrate
- **Generic Name:** nitroglycerin tablets
- **Official Name:** nitroglycerin tablets, U.S.P.
- **Trade Name:** Nitrostat

### ROUTES OF ADMINISTRATION

The route describes how the medication is actually given to or taken by the patient. The route that is chosen controls how fast the medication is absorbed by the body and its effect. Each medication administered by the EMT is prepared in a form that allows for the quickest and safest absorption into the body.

The following are common routes of administration of medications given by the EMT:

- **Sublingual.** The medication is placed under the patient’s tongue. The patient does not swallow the medication. It is dissolved and absorbed across the mucous membrane in the mouth. The drug usually has a relatively quick absorption rate into the blood. The patient must be alert in order for you to administer the medication in this manner. (Medication placed into the mouth of a patient who is not alert or who is unresponsive can become lodged in the airway or aspirated into the lungs.) Only a very limited number of medications are able to be given by the sublingual route. Medications administered by the EMT by the sublingual route are:
  - Nitroglycerin tablets
  - Nitroglycerin spray

- **Oral.** The drug is swallowed. Except for activated charcoal, it is absorbed from the stomach or intestinal tract. The patient must be responsive and able to swallow. The patient may refuse to swallow the drug if it is unpleasant, or may vomit it. Aspirin is first chewed, so that the medication absorption can begin immediately through the oral mucosa, and is then swallowed. Medications administered by the EMT by the oral route are:
  - Aspirin
  - Oral glucose
  - Activated charcoal

### MEDICATION FORMS

Medications come in several different forms. The form usually limits administration to one specific route. This ensures the proper administration of the medication, its correct controlled release, and also the appropriate effect on the target organ or body system. The medication form also determines the effects of the drug. Some drugs have a more local effect on specific cells or organs, whereas other drugs have a much broader, or systemic, effect on the entire body.

Common forms of medications administered by the EMT are:

- **Compressed powder or tablet.** A compressed powder that is shaped into a small disk or elongated shape. Nitroglycerin tablets and aspirin tablets are examples of this type of medication form (Figure 14-1).

- **Liquid for injection.** A liquid substance with no particulate matter. Because epinephrine is injected into the muscle, it is in a liquid form (Figure 14-2).

- **Gel.** A viscous (thick, sticky) substance that the patient swallows. Oral glucose is a gel (Figure 14-3).
• **Suspension.** Drug particles that are mixed in a suitable liquid. These mixtures do not remain mixed for long periods of time and have a tendency to separate. Suspensions must be shaken well prior to administration. Activated charcoal is administered as a suspension (Figure 14-4).

• **Fine powder for inhalation.** This form is actually a crystalline solid that is mixed with liquid to form a suspension. A prescribed metered-dose inhaler carried by the patient for inhalation has medication in this form (Figure 14-5a). Because it is a suspension, it is necessary to shake the canister vigorously prior to administration. The medication appears as a mist or aerosol. Each spray delivers a precise measured amount of drug to the patient.

• **Small-volume nebulizer.** A nebulizer is a device that uses a compressed gas, typically oxygen, that is forced into a chamber containing medication. The gas mixes with the liquid medication and forms an aerosol. The aerosol is inhaled by the patient—either through a mouthpiece or through a face mask (Figure 14-5b)—and the medication is directly deposited on the mucosal lining deep in the respiratory tract. By depositing the medication at the desired site, the effect is more immediate and direct than when given by other routes, and fewer systemic side effects are usually noted.
Instead be in the form of a spray. Nitroglycerin spray is an aerosol that contains nitroglycerin in a propellant. Each spray delivers a precise metered dose.

### ESSENTIAL MEDICATION INFORMATION

It is important that the EMT understand the following terminology associated with the medications to be administered:

- Indications
- Contraindications
- Dose
- Administration
- Actions
- Side effects

We will use the example of nitroglycerin so you can see how the information applies to a medication you will actually be called on to administer. This information is essential to ensure proper, safe, and effective medication administration.

### Indications

The indications for a medication include the most common uses of the drug in treating a specific condition. Indications are geared toward the relief of signs, symptoms, or specific conditions—a direct therapeutic benefit derived from the administration of the drug. For example, an indication for the use of nitroglycerin would be chest pain (because nitroglycerin may relieve chest pain).

### Contraindications

Contraindications are situations in which the drug should not be administered because of the potential harm that could be caused to the patient. In some cases, the drug may not have any benefit to the patient in improving his condition; therefore, the drug should not be given. Low blood pressure is a contraindication for the use of nitroglycerin (because nitroglycerin will lower the blood pressure, possibly causing an already-low blood pressure to become dangerously low). An absolute contraindication indicates that the drug should not be used in this situation or condition under any circumstances, whereas a relative contraindication indicates that the drug is not preferred but can be used if absolutely necessary and no alternative is available.

### Dose

The dose indicates how much of the drug should be given to the patient. It is important to distinguish between adult dosages and dosages for infants and children so that the correct dose is administered. Too much
of the drug could cause serious side effects, whereas an inadequate amount of the drug may have little or no effect. For nitroglycerin, EMTs are advised to administer one dose (one tablet or one spray) and repeat it in 3–5 minutes if there is no relief, to a maximum of three doses (including any doses the patient may already have taken before the ambulance arrived).

**Administration**

**Administration** refers to the route and form in which the drug is given. The EMT will administer medications sublingually, orally, by inhalation, or by injection. Nitroglycerin, for instance, is administered sublingually in tablet or spray form.

**Actions**

The **action** is, in general, the effect the drug has on the body. The **therapeutic effect** is the intended positive response by the body. The **mechanism of action** is how the drug works to create its effect on the body. The action, therapeutic effect, and mechanism of action provide the justification for administering a particular medication. If the action described will not produce the desired effect, then the drug should not be administered. Actions of nitroglycerin include relaxation of blood vessels and decreasing workload for the heart.

**Side Effects**

Even when given appropriately, drugs often have actions that are not desired and that occur in addition to the desired therapeutic effects. These are referred to as **side effects**. (Note that a side effect is not an allergic reaction to the drug.) Some side effects are unpredictable. Other side effects are predictable and are expected upon administration of certain medications. For example, the desired, therapeutic actions of epinephrine are dilation of the bronchioles and constriction of the blood vessels, which will help to relieve a severe allergic reaction. However, epinephrine will also cause an increased heart rate (tachycardia). This is an undesirable side effect of epinephrine. Nitroglycerin’s therapeutic effect is relief of chest pain. Side effects of nitroglycerin include lowering of blood pressure (hypotension), headache, and pulse rate changes.

The EMT must be aware of the potential side effects and be prepared to manage the patient and provide reassurance.

**KEY STEPS IN ADMINISTERING MEDICATIONS**

The following are key steps that must be followed when administering a medication to the patient.

**Obtain an Order from Medical Direction**

Every medication the EMT administers, or assists the patient with, requires an order from medical direction (Figure 14-7). The medication order may be obtained either on-line by direct communication with medical direction by phone or radio, or off-line through protocols or standing orders. It is important to know and understand your local protocols prior to responding to any emergency call.

If you receive an on-line order from medical direction, you must verify it by restating the drug to be administered, the dose, and the route. This reduces the chances that an improper medication is inadvertently administered, the wrong dose is given, or an inappropriate route is used.

It may be necessary for the EMT to make a judgment as to whether the patient can tolerate the administration of the medication. For example, you may have received an on-line order for the administration of oral glucose. The patient was talking incoherently when you called medical direction for the order; however, his mental status has deteriorated, and now he is only responding to painful stimuli. Obviously, administration of oral glucose may lead to aspiration in this patient. Even though the medication order exists, it is now inappropriate to administer the oral glucose to this patient. You should contact medical direction and report the deterioration in the patient’s condition. At the same time, it will be appropriate to seek further orders for emergency care from medical direction.

**Select the Proper Medication**

Once the medication order has been received, it is the EMT’s responsibility to ensure that the proper medication has been selected. You must carefully read the medication label, especially in medications that are
prescribed to the patient, to determine that the medication is consistent with the order. Many medications have several trade names. This may be confusing, since many trade names are very similar. (The various trade names of drugs relevant to emergency care will be identified in later chapters that discuss each particular medication.)

Verify the Patient’s Prescription

When the medication to be given is not carried on the EMS unit and must be obtained from the patient, it is extremely important to verify that the medication is actually prescribed for the patient and not some other individual such as a spouse, relative, or friend. Some patients may take medications that are not specifically prescribed for them. They believe that if the signs and symptoms are similar to those of someone who is taking the medication, then it is appropriate for them to take it also.

For example, you arrive on the scene of a 55-year-old female patient complaining of chest pain. Through your history, you determine that the patient has taken nitroglycerin in the past for similar bouts of chest pain. Your assumption is that the patient must have a prescription for nitroglycerin. However, upon inspection of the name on the prescription label, and following further questioning, you determine that the medication is actually prescribed for her husband. The patient has been taking the medication, not based on a physician’s order, but because she recognized signs and symptoms similar to her husband’s.

As you can see, it may be somewhat misleading when a patient states that he has been taking a medication for a condition or symptom. To avoid medication administration errors, it is vital to check the prescription label and verify the patient’s name. The EMT should never administer medication that is not prescribed for the patient unless ordered to do so by medical direction. For instance, in the case of the patient just mentioned, the EMT would not assist the patient with administration of nitroglycerin unless medical direction issued orders to administer the husband’s nitroglycerin. (For a medication carried on the EMS unit—such as oxygen, oral glucose, or activated charcoal—prescription information is not relevant.)

Some medication labels are not affixed to the medication container itself but are placed on or inside the box or other outer packaging. Nitroglycerin, epinephrine auto-injectors, and metered-dose inhalers are packaged this way. If your patient has one of these medications, you will not be able to tell by looking at the container if the medication has been prescribed for this patient. If the outer packaging cannot be found, you must determine through careful questioning if the prescription truly belongs to the patient.

Check the Expiration Date

Check the medication’s expiration date. Dependent on the type of package and the medication, the expiration date is either printed on the container itself or on the prescription label.

Do not administer expired medication. Properly dispose of the medications according to your state drug or pharmacy guidelines.

Check for Discoloration or Impurities

Epinephrine, or any other medication that comes in liquid form, should be inspected for any discoloration or cloudiness prior to administration. If the medication appears to be cloudy or discolored, or if any particulate material is found in the container, do not use it. Discard the medication.

Verify the Form, Route, and Dose

Be sure the proper drug form is used for the route selected. Verify that the dose to be administered is correct. Check the medication label to ensure it matches the drug order received from medical direction. Some drug packages are similar but contain different doses. For example, the epinephrine auto-injector comes in adult and pediatric sizes. The packages look very similar. Without close inspection it would be easy to mistake one for the other. Administering an adult dose to a child could have detrimental effects, whereas administering a pediatric dose to an adult may have no or little effect.

The drugs are in a form that corresponds to a specific route of administration. Attempting to administer the medication by some other route may lead to ineffective action or potentially harmful side effects.

Medication Administration: The Five “Rights”

Medication administration is a serious role performed by the EMT. As easily as one of the drugs may improve the condition of a patient, the administration of the wrong medication, the wrong route, or the wrong dose may lead to unwarranted effects and possible serious patient deterioration. An easy way to remember what needs to be checked prior to administration of a medication is to use the principle of the “five rights” of medication administration, as follows:

- **Right patient.** You must be sure that the medication you are administering is prescribed for that specific patient. Do not administer medications that are prescribed for anyone other than the patient unless ordered by the medical direction physician. If the medication to be administered is one that is carried on the EMS unit, the EMT must make the judgment whether this medication is right for this particular patient.
- **Right medication.** Once you have determined what medication is appropriate to administer to the patient,
it is vital to be sure that the medication being administered is actually the medication that is intended to be administered. Many patients put several different types of medications into one prescription bottle. Be sure that you have selected the correct medication before administering it to the patient.

- **Right route.** After determining you have the right drug for the right patient, be sure to administer the medication by the right route. The route may be oral, sublingual, inhalation, or intramuscular injection. Administering the drug by the wrong route may have deleterious effects or no effect on the patient. For example, having the patient swallow a nitroglycerin tablet will end with no substantial clinical effect on the patient.

- **Right dose.** When administering a medication, you must know the appropriate dose for the patient. Be sure to understand differences in doses for adults and children. By not knowing the proper dose of the medication, you may underdose the patient, resulting in the medication having little effect, or you may overdose the patient by administering too much of the drug. The overdose may cause serious harm. Once the drug is “on board,” there is no way to retract it if too much is administered. You must wait out the period and hope the patient does not suffer serious consequences from your action.

- **Right date (time).** Always check the expiration date of the medication. Do not administer drugs that are expired. The drug expires on the first day of the month listed unless otherwise specified. Once the drug is expired, it does not typically change its composition but weakens in strength and its effectiveness in achieving the desired action.

The “five rights” will help you remember what must be checked prior to medication administration. *Take your role very seriously when administering any type of medication.*

### Documentation

Once you administer the medication, you must document the drug, dose, route, and time the medication was administered. Report any changes in the patient’s condition, and report whether the signs or symptoms have been relieved. Also report any deterioration in the patient’s condition or if side effects associated with the drug have occurred.

### REASSESSMENT FOLLOWING ADMINISTRATION

#### ASSESSMENT TIPS

Once a medication has been administered, it is important to reassess the patient to determine if there is any change in the condition. Aspirin and activated charcoal may not produce obvious changes in the patient’s condition.

Following the administration of a medication, it is necessary to perform a reassessment. During the reassessment, repeat measurement of vital signs and assess for any changes in the patient’s condition.

Assess the following and document changes after drug administration:

- Mental status
- Patency of the airway
- Respiratory rate and quality
- Pulse rate and quality
- Skin color, temperature, and condition
- Blood pressure
- SpO₂ reading
- Change or relief of the patient’s complaints
- Relief of signs and symptoms associated with the patient’s complaints
- Medication side effects
- Improvement or deterioration in the patient’s condition following medication administration

During the reassessment, be sure to check the adequacy of oxygen administration, whether it is being delivered by a nasal cannula, simple face mask, non-rebreather mask, or in conjunction with positive pressure ventilation. In addition to the medication that was administered, assess the adequacy of any other care that has been administered to manage the patient’s condition. Based on the care provided, determine if improvement or deterioration in the patient’s condition has occurred. Document any improvement or deterioration.

### SOURCES OF MEDICATION INFORMATION

The following are sources you can use to gather more information about specific medications. These sources may also provide valuable information relevant to the patient’s prescription medications:

- American Hospital Formulary Service, published by the American Society of Hospital Pharmacists
- AMA Drug Evaluation, published by the American Medical Association Department of Drugs
- Physicians’ Desk Reference (PDR), published yearly by the Medical Economics Data Production Company
- Package inserts—information that is packaged with the particular drug
- Poison control centers
- EMS pocket drug reference guide
- ePocrates for the PDA
- Other on-line sources approved by your medical director
SUMMARY

Administration of medication is a very serious part of the EMT’s responsibility. As much as a medication might help a patient and relieve pain and suffering or potentially relieve a condition, it can be harmful or fatal if administered to the wrong patient or for the wrong condition. The medications that the EMT will carry on the ambulance are oxygen, oral glucose, activated charcoal, and aspirin. The patient-prescribed medications that the EMT may assist the patient with taking are a beta2 agonist by metered-dose inhaler or small-volume nebulizer, nitroglycerin, and epinephrine.

Medications can be administered via various routes, including sublingual, oral, inhalation, and injection. Injection provides the most rapid absorption into the body. The medication itself may come in the form of a compressed powder or tablet, liquid for injection, gel, suspension, fine powder for inhalation, gas, spray, or vaporized liquid in a fixed-dose nebulizer.

Before administering any medication, you must understand the indications, contraindications, dose, administration route and form, actions, and side effects. Be sure to obtain the appropriate order from medical direction, whether off-line or on-line, depending on your protocol. Follow the “five rights” of medication administration: right patient, right medication, right route, right dose, and right date (time). Following the administration of any medication, perform a reassessment to determine if there is any change in the patient’s condition.

Case Study Follow-up

Scene Size-up
You have been dispatched to the scene of an elderly male complaining of chest pain. You and your partner enter the darkened scene cautiously and find the patient sitting against the wall on the floor of the hallway. The phone is off the hook and lying next to the patient. You turn on the hallway lights and scan the scene. The scene appears to be safe. You notice a prescription bottle of nitroglycerin on the table next to the patient. He complains, “I have this crushing pain in my chest. I’ve never experienced pain like this before.” You ask, “What is your name, sir?” He responds, “Jack Brookline.”

Primary Assessment
Your general impression is that of an elderly male patient in severe distress from chest pain. His skin is pale, sweaty, and cool to the touch. His airway is open, breathing is approximately 20 per minute and full, and the radial pulse is 80 per minute and strong. You immediately attach the pulse oximeter to obtain a baseline oxygen saturation reading that is 93% on room air. You apply a nasal cannula at 4 lpm.

Secondary Assessment
The history reveals chest pain that occurred suddenly as the patient was sleeping on the couch. Mr. Brookline was tired and was taking a nap when the pain started. It woke him from his sleep. He got up to get his nitroglycerin off the table in the hallway, but the short walk greatly intensified the pain and caused him to collapse to the floor. He describes the pain as “crushing, like I’ve never experienced before.” The pain does not radiate and is described as 10 on a scale of 1 to 10, with 10 being the worst. The pain began about 10 minutes prior to his call to 911.

Mr. Brookline denies having any allergies and has a prescription of nitroglycerin related to his past medical history of angina, or recurring chest pain. He states that he had a cup of coffee and a sandwich at about 6:00 P.M. He denies doing anything unusual today or prior to the onset of the chest pain.

You obtain a set of baseline vital signs. The blood pressure is 140/100 mmHg; the radial pulse is 104 per minute and regular; the skin is pale, moist, and cool; the breathing is 20 per minute with good volume; the SpO2 is 97% on the nasal cannula at 4 lpm.

You ask, “Mr. Brookline, did you take any nitroglycerin before we arrived?” He states, “No, once I sat down in the hallway, I couldn’t reach it.” You also ask if he is taking any medication for erectile dysfunction, to which he answers “no.”

After having the patient chew 160 mg of aspirin, you contact medical direction by radio for permission to administer the nitroglycerin to Mr. Brookline. You report the physical findings, history, and baseline vital signs. Medical direction orders, “Administer one tablet sublingually, recheck the blood pressure within 2 minutes, and reevaluate the intensity of the chest pain. If the chest pain does not subside after 5 minutes and the systolic blood pressure remains greater than 90 mmHg, administer a second tablet and reassess the blood pressure and the chest pain intensity.” You repeat the order to medical direction and sign off.

You inspect the medication container, checking the medication name to make sure it is really nitroglycerin, the patient’s name to make sure it is prescribed to continued
Case Study Follow-up continued

Jack Brookline, and the expiration date to be sure the prescription is current.

You instruct, “Mr. Brookline, I need you to open your mouth and lift your tongue. I am going to place a nitroglycerin tablet under your tongue. Do not swallow the tablet and be sure to keep your mouth closed until it is completely dissolved. It may burn slightly and you may get a headache.” With a gloved hand you place a nitroglycerin tablet under his tongue. You record the medication administered, dose, route, and time.

Reassessment

After 2 minutes, Mr. Brookline’s blood pressure is 110/60 mmHg—lower than before, but still in the normal range. Mr. Brookline indicates that the pain has subsided greatly. On a scale of 1 to 10, the pain is now a 2 or a 3. His radial pulse remains strong at 82/minute, and his breathing is normal at 18/minute and of good volume. His skin is now slightly warmer, less moist, and more normal in color. You check the oxygen to ensure that it is flowing adequately. His SpO₂ is now 99% while on the nasal cannula at 4 lpm.

You place Mr. Brookline on the stretcher and move him to the ambulance for transport, making sure to transport the medication along with him. You reassess the vital signs and determine that the chest pain is almost completely gone. You record the vital signs, contact the receiving medical facility, and give a report.

Upon arrival at the hospital, Mr. Brookline is transferred without incident. He now appears to be resting comfortably and in better spirits, even managing to say a hearty, “Thanks, guys, for helping me out.” You complete the necessary EMS report and prepare the unit for another call.

IN REVIEW

1. Name the medications that are carried on the EMS unit.
2. Name the medications an EMT may administer or assist in administering if prescribed for the patient.
3. Name four routes by which medications may be administered by the EMT.
4. Name several common forms of medications that may be administered by the EMT.
5. Define the following six terms related to medications:
   • indications
   • dose
   • actions
   • contraindications
   • administration
   • side effects
6. Describe the key steps to follow in administering a medication to a patient.
7. Describe proper reassessment following administration of a medication.

CRITICAL THINKING

You arrive on the scene and find a 46-year-old male patient who is complaining of shortness of breath and chest discomfort after exercising on the treadmill at the gym. The patient is alert and oriented. His respirations are 22 per minute with a good tidal volume. His radial pulse is 102 bpm and the skin is pale, cool, and clammy. He states that the pain started about 15 minutes prior to the end of his workout. It got so bad he had to stop working out. He felt light-headed and nauseated. He has had no relief in the pain and he reports that it continues to worsen. He describes the pain as a “tightening” feeling in the middle of his chest. He states he also feels an aching-type pain down the medial aspect of both arms. The pain is an 8 on a 1-to-10 scale, with 10 being the worst. It has now been approximately 30 minutes since the onset of the pain. His blood pressure is 138/92 mmHg, and his SpO₂ is 95% on room air. He has no previous significant medical history and takes no medication. He denies any allergies. He had a sports drink about 45 minutes prior to your arrival.

1. What medications might you consider administering in this patient?
2. What medication would the patient possibly have on his person?
3. What are the forms of the medications that you would possibly administer to this patient?
4. Why are those forms of medications used?
5. What information must you understand about the medication prior to administering it?
6. What are the possible ways to obtain an order for the medication from medical direction?
7. What are the five “rights” you would check prior to administering the medication?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Shock and Resuscitation**

**COMPETENCY •** Applies fundamental knowledge of the causes, pathophysiology, and management of shock, respiratory failure or arrest, cardiac failure or arrest, and post-resuscitation management.

**OBJECTIVES •** After reading this chapter, you should be able to:

15-1. Define key terms introduced in this chapter.
15-2. Explain the pathophysiology of shock (hypoperfusion), including the consequences of cellular hypoxia and death.
15-3. Describe the physiology of maintaining adequate perfusion.
15-4. Describe how inadequate vascular volume, inadequate heart function, and decreased peripheral vascular resistance can lead to shock.
15-5. Give examples of conditions that can lead to:
   a. Loss of vascular volume
   b. Inadequate heart function
   c. Decreased peripheral vascular resistance
15-6. Explain the mechanisms and pathophysiology of each of the following categories and types of shock:
   a. Hypovolemic (hemorrhagic and nonhemorrhagic)
   b. Distributive (anaphylactic, septic, neurogenic)
   c. Cardiogenic
   d. Obstructive
   e. Metabolic or respiratory
15-7. Explain how compensatory mechanisms to shock are maintained through:
   a. Direct nerve stimulation
   b. Release of hormones
15-8. Explain the body’s compensatory responses to hypoperfusion and how they manifest in the early signs and symptoms of shock.
15-9. Differentiate between early (compensatory) and late (decompensatory/irreversible) signs of shock.
15-10. Describe the progression of shock through the compensatory, decompensatory (progressive), and irreversible stages.
15-11. Explain how to identify the patient who is in a shock state and demonstrate the assessment of patients to identify shock.
15-12. Explain the influence of age on the assessment and management of patients with shock.
15-13. Discuss the goals of prehospital management of patients with shock.
15-14. Describe the pathophysiology of cardiac arrest.
15-15. Differentiate between the electrical, circulatory, and metabolic phases of cardiac arrest.
15-16. Identify situations in which resuscitative attempts should be withheld.
15-17. Explain each of the links in the Chain of Survival of cardiac arrest for the adult and pediatric patient.
15-18. Explain the importance of early defibrillation in cardiac arrest.
15-19. Explain the rationale for the “push hard and push fast” approach to cardiopulmonary resuscitation (CPR).
15-20. Describe the features, functions, advantages, disadvantages, use, and precautions in the use of automated external defibrillators (AEDs).
15-21. Compare and contrast ventricular fibrillation, ventricular tachycardia, asystole, and pulseless electrical activity.
15-22. Given a series of cardiac arrest scenarios involving infants, children, and adults, demonstrate appropriate assessment and resuscitative techniques, including the integrated use of AEDs (automated and semiautomated), ventilation, and CPR, and explain the purpose and procedure for reassessment of the cardiac arrest patient.
15-24. Given a cardiac arrest scenario, make decisions regarding obtaining advanced cardiac life support (ACLS).
15-25. Describe the safety precautions to be taken to protect yourself, other EMS providers, the patient, and bystanders in resuscitation situations.
15-26. Explain the importance of AED maintenance, EMT training and skills maintenance, and medical direction in the Chain of Survival of cardiac arrest.

*continued*
15-27. Discuss special considerations in the use of an AED in patients with cardiac pacemakers and automatic implanted cardioverter-defibrillators.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

---

**Case Study**

**The Dispatch**
EMS Unit 102—respond to 46 Hillman Street. You have a 26-year-old male patient who has been stabbed in the leg and is bleeding profusely. Law enforcement is en route. Time out is 2102 hours.

**Upon Arrival**
You and your partner arrive at the scene and are directed into the house by a police officer. He leads you into the basement where you find the patient lying supine on the floor with a large pool of blood around his right thigh. His pant leg is completely soaked in blood. The patient is not alert and doesn’t respond when you call out to him. He appears to be extremely pale.

**How would you proceed to assess and care for this patient?**
During this chapter, you will learn about assessment and emergency care for a patient suffering from shock and those needing resuscitation. Later, we will return to the case and apply the procedures learned.

---

**INTRODUCTION**

Shock is a critical condition that results in the inadequate perfusion of cells, tissue, and organs. It carries a high morbidity and mortality if it is allowed to progress. If shock is not managed effectively, it will eventually lead to cell injury, organ dysfunction, multisystem organ failure, and patient death. Every cell, tissue, organ, and organ system can be affected by shock. In a shock state, the body attempts to restore homeostasis through a response of the nervous system and release of hormones, which cause many of the signs and symptoms seen in the shock patient. There are many different etiologies and types of shock. Determining the underlying cause is important to providing effective emergency care.

Resuscitation is the emergency care process that attempts to restore lost vital functions. It focuses on managing the airway, oxygenation, ventilation, and circulation. Resuscitation is most often associated with cardiac arrest; however, it is also performed in cases of respiratory failure, respiratory arrest, shock, and many other conditions.

**SHOCK**

Shock is defined as inadequate tissue perfusion. It is also often referred to as hypoperfusion. During a shock state, inadequate amounts of oxygen and glucose are delivered to cells. The inadequacy is defined as an amount of oxygen delivered to the cells that is less than the amount required for normal metabolism. In addition, an impaired elimination of carbon dioxide and other waste products occurs.

As discussed in Chapter 8, “Pathophysiology,” a lack of oxygen in the cell causes a shift from aerobic
to anaerobic metabolism. Aerobic metabolism takes a glucose molecule and breaks it down in the presence of oxygen, yielding the large amount of adenosine triphosphate (ATP) that is necessary for energy production along with water and carbon dioxide as by-products. The waste carbon dioxide is transported in the venous blood back to the heart and lungs, where it is eliminated during exhalation. When there is a lack of available oxygen, anaerobic metabolism takes place that results in a drastically lower production of ATP and the creation of lactic acid as a by-product.

Energy is needed to maintain the function of the cell’s sodium/potassium pump. If the pump fails, the sodium is no longer removed from the cell in exchange for potassium. Potassium and lactic acid leave the cell and begin to collect in the interstitial fluid and eventually enter the blood. The sodium collects inside the cell and attracts water. As a result, the cell swells and eventually ruptures and dies. The acid that has been liberated causes the failure of enzyme systems and the release of lysozymes. The lysozymes begin to autodigest the cell, leading to cell death and eventual organ death.

Restoring perfusion (oxygen and glucose delivery) will restore production of the larger amounts of energy required, reverse the lactic acid buildup, and re-establish the function of the sodium/potassium pump. In order to be effective, restoration of perfusion must be accomplished before a critical mass of cell death occurs.

In order to maintain cellular perfusion, several components must be functioning adequately. One of the most important is the ability of the body to deliver an adequate amount of oxygen to the cells. For this to happen, the following components associated with oxygen delivery and perfusion must be intact:

- The patient must be breathing an adequate concentration of oxygen (FiO₂) with each breath. If the oxygen content of the ambient air that is being inhaled is diminished, the amount of oxygen in the alveoli available for gas exchange will also be decreased. By increasing the oxygen concentration of inhaled air through oxygen therapy, more oxygen will be made available in the alveoli for gas exchange.
- The oxygen in the alveoli must diffuse across the alveolar/capillary membrane to enter the capillary and be transported to the cells. If there is a disturbance in the ability of the oxygen to diffuse into the capillary, the blood oxygen content would be diminished.
- Once the oxygen diffuses across the capillary, it has to be transported to the cells. Only a small amount (1.5 to 3 percent) of oxygen dissolves into the plasma. The majority of oxygen must bind with hemoglobin in the red blood cells. If an inadequate number of red blood cells contain hemoglobin, the oxygen-carrying capacity of the blood will be decreased. This will result in a decrease in the delivery of oxygen to the cells.
- Once the oxygen has effectively bonded with hemoglobin, there must be an adequate volume of blood and pressure to move the blood forward through the systemic circulation, enabling it to be delivered to the cells.
- When the oxygen-saturated hemoglobin reaches the cell, the oxygen must break its bond, be released from the hemoglobin, and diffuse across the capillary and into the cell. If a condition exists that causes the oxygen to remain bound to the hemoglobin, the blood will appear to be well oxygenated but the cells will become severely hypoxic.

Most of the emergency care of the patient in shock is geared toward maintaining or restoring oxygen and glucose delivery to the cells. As you can gather from the aforementioned list of necessary components, some of the disturbances of oxygen delivery are not effectively managed in the prehospital setting—for example, increasing the amount of red blood cells and hemoglobin to restore or improve the blood’s oxygen-carrying capability. This requires the administration of red blood cells and hemoglobin, which is generally not a prehospital function. Thus, a patient who presents in shock must be categorized as critical and unstable and considered for expeditious transport following the primary assessment and initial emergency care.

**Etiologies of Shock**

Three basic etiologies of shock will be described in this section. These etiologies are the basis for the categories and types of shock that will be defined later. The etiologies also provide a foundation for the general emergency care necessary to manage a shock patient as well as an understanding that not all shock treatment is the same.

Poor tissue perfusion (shock) is typically due to one or more of the following basic etiologies:

- **Inadequate volume.** A patient who has a decreased blood volume will have a decrease in preload which, in turn, will cause the stroke volume and cardiac output to fall. A decrease in cardiac output will cause a drop in the systolic blood pressure. As you recall, the systolic blood pressure is responsible for transporting the oxygenated blood throughout the systemic circulation. Therefore, a decrease in systolic blood pressure can result in inadequate tissue perfusion.

  A decrease in blood volume may result from the loss of whole blood, which includes the formed elements (red blood cells, white blood cells, and platelets) and plasma (Figure 15-1), or from loss of plasma volume alone. Bleeding causes whole blood loss, whereas diarrhea, burns, excessive urination, increased capillary leakage, and excessive vomiting are examples of conditions that cause loss of plasma volume alone.

  The patient who is in shock from inadequate volume obviously needs an increase in blood volume to restore adequate perfusion. However, if the patient lost whole blood from hemorrhage, there has been
a loss of oxygen-carrying capability of the blood in addition to the decrease in pressure and perfusion. This patient would benefit most from administration of packed red blood cells and fluids, which would increase the oxygen-carrying capability of the blood as well as improving pressure and perfusion. If only fluid is administered, the pressure and perfusion may be improved, but the cells may remain hypoxic because there still are not enough red blood cells and hemoglobin to carry the needed amount of oxygen.

On the other hand, consider a patient who is in shock from fluid depletion resulting from excessive diarrhea. No red blood cells were lost in the diarrhea, only large amounts of water and some electrolytes. The patient has enough red blood cells and hemoglobin available to carry oxygen; however, his depleted fluid volume has decreased the blood pressure and ability of the blood to deliver the oxygen to the cells. This patient does not need whole blood, but does need to have the fluid or water portion of his blood restored. This is also typical in the burn patient who has lost plasma from the burned areas but still has adequate red blood cells and hemoglobin. This patient, too, needs fluid but does not need whole blood.

• Inadequate pump function. The heart is the pump responsible for generating the force necessary to move the blood throughout the body. If the pump fails, regardless of the blood volume, the delivery of oxygen and glucose to cells will be decreased (Figure 15-2). Pump function failure may result from an injury to the heart that reduces its ability to generate contractions strong enough to push the blood forward throughout the body. For example, a heart attack (myocardial infarction) deadens a portion of the heart muscle. Like any other muscle, a portion that is dead doesn’t contribute to the force of contraction. If the heart attack has affected a large enough area of heart muscle, the pump will fail and lead to a shock state. A heart attack is not the only condition that can cause pump failure. The heart may be weakened over time from disease, old age, or injury and fail to adequately pump the blood. This is often seen in congestive heart failure patients, resulting in an inadequate delivery of oxygen and glucose to the cells. Heart valve disease and cardiac rhythm disturbances may also reduce the ability of the heart to eject the blood effectively, leading to pump failure.

Mechanical obstruction of the movement of blood into the heart may also contribute to pump failure. For example, the heart chambers may be compressed from a collection of blood in the pericardial sac, the fibrous sac that surrounds the heart. If the chambers are compressed, the ventricular filling space is decreased, leading to a decrease in preload. This condition is referred to as pericardial tamponade. Another condition that leads to a decrease in preload from compression and poor filling is a tension pneumothorax. This results from an injury to the lung that permits a large collection of air in the pleural space of one hemithorax. As the air continues to collect in the pleural space, it builds pressure and pushes the mediastinum toward the uninjured lung. This causes the inferior vena cava to kink and the aorta and heart to be compressed, resulting in a decrease in preload. A decrease in preload causes a drop in stroke volume and cardiac output, which in turn reduces blood pressure and perfusion. Pericardial tamponade and tension pneumothorax will be discussed in greater detail in Chapter 34, “Chest Trauma.”

As just described, ineffective pump function can result either from damage to the heart or from a mechanical obstruction. In either condition, the patient requires improvement of pump function to eliminate the shock state. Remember, this patient has not lost any blood volume. With pump failure, administering fluids will not improve the condition and may actually make it worse.

• Inadequate vessel tone. In order to have an adequate blood pressure, the tone of the vessels must be maintained. The tone is related to the size of the vessel and the resistance created within it and is referred to as the systemic vascular resistance or peripheral
vascular resistance. Recall from the pathophysiology chapter that as vessel size decreases, resistance increases. The result is an increase in the blood pressure (BP), which is governed by both cardiac output (CO) and systemic vascular resistance (SVR): (BP = CO × SVR). Conversely, if the vessel size increases because of massive vasodilation, the resistance decreases and the blood pressure and perfusion also decrease. In this case, the patient has not lost any blood volume; however, there is no longer enough intravascular blood volume to fill the vascular space because of the increase in vessel size (Figure 15-3 ■).

The result is a decrease in vascular resistance with a decrease in blood pressure and perfusion. The pumping function of the heart is normal, but the relative reduction in blood volume returning to the left ventricle will reduce preload, reduce cardiac output, and further decrease blood pressure and perfusion.

The sympathetic nervous system provides tone by keeping the vessel size regulated to a certain size to maintain the resistance and pressure. Therefore, inadequate vessel tone may occur if the sympathetic nervous system stimulation of the vessels is lost because of an injury to the spinal cord. Another cause of inadequate vessel tone may be chemical mediators released within the body that cause a systemic dilation of vessels. In either case, the only way to increase the blood pressure and perfusion is to decrease the size of the vessel through vasoconstriction to restore resistance or to fill the vessel with more volume to increase the internal vessel pressure. Typically, both approaches—vasoconstriction and volume restoration—are used in an emergency care for cases in which both blood pressure and perfusion are extremely poor.

As you can see, it is not only the cause of shock but also the needed emergency care that may vary, depending on the etiology: inadequate volume, inadequate pump function, or inadequate vessel tone—or a combination of these. A treatment that is effective for low blood pressure and poor perfusion based on one etiology of shock may worsen the condition from another etiology. Many emergency care procedures for shock are beyond the scope of the EMT; however, it is vital that an EMT recognizes a shock state, provides appropriate emergency care, and initiates rapid transport.

In some cases, it may be highly desirable to contact an advanced life support unit that has medications, intravenous fluids, and procedures that can restore the pressure, perfusion, cellular oxygenation, and delivery of glucose to cells. Keep in mind, however, that ALS is also limited in some cases, and delaying or interrupting transport may worsen the patient outcome. This is especially true for patients who are in shock from blood loss. ALS units typically carry only water-based fluids with electrolytes that do not have the capability to transport oxygen. Using these fluids in the patient who continues to bleed may cause the injury to bleed faster from the fluid infusion that is increasing the pressure and making the blood less viscous. In these cases it is critical to get the patient to a medical facility as expeditiously as possible.

Categories of Shock

There are four major categories of shock and a fifth category that some sources list (Figure 15-4 ■). These categories are a further classification of the etiology and are somewhat more descriptive. The category of shock provides insight not only into the cause but also into the treatment necessary to reverse the shock state.

**Hypovolemic Shock**

If you break down the word *hypovolemic* based on what you learned in the medical terminology section of Chapter 7, “Anatomy, Physiology, and Medical Terminology,” it clearly defines the cause of the shock.
Hypovolemic shock means shock that is caused from a low blood volume. Hypovolemic shock is the most common form of shock. It can be due to blood loss or loss of some other fluid—basically any condition or injury that decreases the blood content or the fluid portion of the blood. The most common cause of hypovolemic shock is hemorrhage (Figure 15-5a ■). Hemorrhage refers specifically to the loss of whole blood. This may be due to an injury, such as a laceration to a vessel or organ, or to a medical illness, such as bleeding from the gastrointestinal tract. Nonhemorrhagic forms of hypovolemia are associated with fluid loss from burns and dehydration (Figure 15-5b ■). Hypovolemic shock will be further discussed later in the chapter.

**Distributive Shock**

Distributive shock is associated with a decrease in intravascular volume caused by massive systemic vasodilation and an increase in capillary permeability.
In massive systemic vasodilation there is usually no actual loss of fluid or blood from the vessels but rather a relative reduction in volume—that is, a volume that has become inadequate to fill the increased size and capacity of the vessels. In some conditions, however, not only will the vessels dilate but also the capillaries will become permeable, which allows fluid to leak out of the capillaries and into the interstitial space. This causes an actual fluid loss, because the fluid is moving out of the vessels and into the spaces between the cells. If treated properly, the fluid will eventually re-enter the vessels.

In distributive shock, the shock state is caused by a reduction in systemic and peripheral vascular
resistance that contributes to a reduction in the systolic blood pressure. Fluid leakage from the capillaries and vasodilation cause a reduction in the preload, which in turn reduces the stroke volume, cardiac output, and systolic blood pressure. The result is a decrease in tissue perfusion.

Cardiogenic Shock

Cardiogenic shock is caused by ineffective pump function of the heart. The patient has an adequate blood volume and vessel tone; however, hypoperfusion results from the inability of the heart to contract effectively. Typically, when more than 40 percent of the left ventricle has been lost, cumulatively, because of damage from a heart attack (Figure 15-7  ■), congestive heart failure, infection, or abnormal heart rhythms, the patient is prone to cardiogenic shock. The heart muscle that is lost no longer contributes to the force of contraction. When the left ventricle fails to generate enough force to eject sufficient blood from the chamber into the systemic circulation, the result is a reduction in stroke volume, cardiac output, and systolic blood pressure, leading to poor tissue perfusion.

Obstructive Shock

Obstructive shock results from a condition that obstructs forward blood flow. The volume is adequate, the heart is not damaged, and the vessels are of a normal size with adequate resistance. However, an obstruction is not allowing the blood to move forward. For example, a large clot that obstructs blood flow in the lungs (pulmonary embolism) will prevent an adequate amount of blood from getting to the left atrium and, subsequently, the left ventricle (Figure 15-8a  ■). This will reduce the preload and in turn decrease the stroke volume, cardiac output, systolic blood pressure, and tissue perfusion.

Two other conditions often associated with injury that can lead to obstructive shock are tension pneumothorax and pericardial tamponade (Figures 15-8b and 15-8c  ■). Both of these conditions, as previously described, compress the heart and prevent adequate ventricular filling. This reduces the preload, stroke volume, cardiac output, systolic blood pressure, and tissue perfusion. Once the pressure is relieved, the heart regains its normal function. Although the pump function of the heart is disturbed, once the condition is reversed and the pressure on the heart is relieved, it functions normally.

Metabolic or Respiratory Shock

Some sources list metabolic shock or respiratory shock as a fifth category of shock—in addition to hypovolemic, distributive, cardiogenic, and obstructive shock. This
Specific Types of Shock

The categories of shock can be further broken down into specific types (review Figure 15-4). The category and etiology primarily describe the immediate reason for the poor perfusion state, whereas the type of shock indicates the initial cause such as blood loss, spinal cord injury, or allergic reaction. Understanding the specific type of shock will allow you to recognize particular signs and symptoms of the various conditions and provide specialized emergency care in some cases.

Hemorrhagic Hypovolemic Shock

Hemorrhagic hypovolemic shock, often referred to simply as hemorrhagic shock, results from the loss of whole blood from the intravascular space. The term hemorrhagic specifically indicates whole blood loss that can occur as a result of a traumatic injury or a medical illness. Organ, vessel, and soft tissue injury are examples of traumatic injury that can cause hemorrhagic shock. Medical causes of hemorrhagic shock may include gastrointestinal bleeding, uterine bleeding, aortic disease, ectopic pregnancy, and esophageal disease.

The key to understanding hemorrhagic hypovolemic shock is the loss of whole blood. Once whole blood is lost, there is not only a decrease in perfusion from a reduction in pressure but also a decrease in the oxygen-carrying capability of the blood from the loss of red blood cells and hemoglobin. The poor perfusion state is from an inadequate intravascular volume.

Stopping the bleeding is the first step in management of this patient. This type of shock often requires the administration of whole blood or blood components to replace the intravascular blood volume that was lost. Thus, this patient requires immediate transport.

Nonhemorrhagic Hypovolemic Shock

Nonhemorrhagic hypovolemic shock is caused by the loss of fluid from the intravascular space; however, red blood cells and hemoglobin remain within the vessels. It is primarily water, plasma proteins, and electrolytes that are lost in nonhemorrhagic hypovolemic shock. This reduces the blood volume, pressure, and perfusion of cells; however, the oxygen-carrying capability of the remaining blood is preserved. The poor perfusion state is from an inadequate intravascular volume. Examples of nonhemorrhagic causes of shock include severe diarrhea, vomiting, excessive sweating, and excessive urination.

Administration of intravenous fluids may be beneficial in this patient; therefore, you might consider advanced life support backup. Always follow your local protocol.

Burn Shock

Burn shock is a specific form of nonhemorrhagic hypovolemic shock resulting from a burn injury. Burns may interrupt the integrity of the capillaries and vessels and allow them to leak plasma and plasma proteins. The skin plays a major role in regulating fluid retention in the body; thus burns may disrupt the body’s fluid balance. Recall from Chapter 8, “Pathophysiology,” that hydrostatic pressure exerts a “push” effect and plasma proteins exert a “pull” effect on fluid inside the capillary. When the capillary is damaged from a burn, it becomes permeable. The push from hydrostatic pressure forces fluid outside of the capillary and into the interstitial space. The damaged capillary allows plasma proteins to leak out and collect in the interstitial space. The pull effect of the plasma proteins that are outside the vessel draws fluid out of the capillary and into the interstitial space and does not allow it to return to the inside of the vessel. This collection of fluid causes the edema seen in the burn patient and leads to burn shock. The shock is a direct result of inadequate intravascular volume.

The key emergency care in the burn patient is to establish and maintain an adequate airway, ventilation, and oxygenation. Also, prevent further contamination of the burn injury. Most burn patients die in the prehospital setting from airway obstruction, inadequate ventilation, or toxic exposure. Burn shock takes several hours to occur. Burns and burn management are covered in detail in Chapter 29, “Burns.”

Anaphylactic Shock

Anaphylactic shock is a type of distributive shock. Anaphylactic reactions are covered in detail in Chapter 21, “Anaphylactic Reactions.” Chemical mediators that are released in the anaphylactic reaction cause massive and systemic vasodilation. These chemical mediators also cause the capillaries to become very permeable and to leak. The hydrostatic pressure inside the capillary forces (pushes) the fluid out into the interstitial space. The dilated vessels cause a reduction in the
systemic vascular resistance, resulting in a decrease in blood pressure and perfusion. The loss of fluid from the capillary further reduces the intravascular volume, causing the preload, stroke volume, cardiac output, systolic blood pressure, and perfusion to decrease, resulting in a shock state.

Epinephrine is the medication of choice in the anaphylactic shock patient. Recall from Chapter 7, “Anatomy, Physiology, and Medical Terminology,” that epinephrine contains alpha properties that cause systemic vasoconstriction. The vasoconstriction reduces the vessel size and increases the resistance, which results in an increase in blood pressure and perfusion. In addition, the vasoconstriction tightens the capillaries and lessens the fluid leakage. Airway management, ventilation, and oxygenation are also key components of the emergency care of the anaphylactic reaction patient.

**Septic Shock**

*Septic shock* is another type of distributive shock. It results from an infection that releases bacteria or toxins in the blood, causing the vessels throughout the body to dilate and become permeable. Fluid leaks out of the vessels into the interstitial space. The shock state is created by the massive vasodilation, which reduces the systemic vascular resistance, blood pressure, and perfusion. Also, the loss of fluid reduces the intravascular volume and decreases the preload, stroke volume, cardiac output, systolic blood pressure, and perfusion.

As an EMT, you will focus on managing the airway, ventilation, and oxygenation. This patient would benefit from intravenous fluids and medication to constrict the vessels. Thus, consider contacting an advanced life support unit. Always follow your local protocol.

**Neurogenic Shock**

*Neurogenic shock,* also commonly referred to as *vasogenic shock,* is another type of distributive shock. Spinal cord injury is a cause of neurogenic shock. A spinal cord injury may damage the sympathetic nerve fibers that control vessel tone below the level of injury. Loss of sympathetic tone causes the vessels to dilate. If the injury is high in the thoracic spinal cord or in the cervical region, enough vessel tone may be lost to cause a drop in systemic vascular resistance, blood pressure, and perfusion. There is no fluid loss from the intravascular space. The drop in perfusion is solely from widespread vasodilation. Blood will begin to pool in the peripheral vessels, causing a decrease in the preload, stroke volume, cardiac output, and systolic blood pressure, causing a further decrease in perfusion.

Emergency care focuses on spinal immobilization and management of the airway, ventilation, and oxygenation. This patient may also benefit from intravenous fluids to fill the vascular space and medication to constrict the vessels. Consider contacting an advanced life support unit. Again, always follow your local protocol.

**Cardiogenic Shock**

Cardiogenic shock is both a category and a type of shock. It is most often due to an acute myocardial infarction (heart attack), congestive heart failure, abnormal cardiac rhythm, or overdose on drugs that depress the pumping function of the heart such as beta blockers or calcium channel blockers. The depressed pump function reduces the force of the left ventricular contraction, stroke volume, cardiac output, systolic blood pressure, and perfusion.

Emergency care focuses on management of the airway, ventilation, and oxygenation. The patient may benefit from intervention and medications administered by an advanced life support unit. Follow your local protocol.

**The Body’s Response to Shock**

When shock occurs, the body attempts to compensate for the disturbance and return the perfusion and tissue function to a normal state. Many of the signs and symptoms the patient exhibits while in shock are related to the compensatory mechanisms. The sympathetic nervous system plays a significant role in trying to restore a normal blood pressure and reverse the shock state.

Recall the function of the baroreceptors from Chapter 8, “Pathophysiology.” These are stretch-sensitive receptors that continuously measure the pressure inside the aorta and carotid arteries. When there is a reduction in blood volume or pump function, or when there is a massive vasodilation with a redistribution of blood volume away from the core circulation, the cardiac output decreases. This causes a decrease in pressure inside the aorta and carotid arteries, which results in a reduction in stretch or tension in the arterial walls. The baroreceptors sense the reduction in arterial wall tension and trigger compensatory mechanisms.

The compensatory mechanisms associated with shock are initiated and maintained through two major pathways: direct sympathetic nerve stimulation and the release of hormones.

**Direct Nerve Stimulation**

When shock occurs, the sympathetic nervous system is activated and stimulates primarily the vessels and the heart in an attempt to restore the blood pressure in the arteries. The effects of the sympathetic stimulation, which occur immediately, are:

- Increase in heart rate
- Increase in force of ventricular contraction (stroke volume)
Vasoconstriction
Stimulation of the release of epinephrine and norepinephrine from the adrenal gland

The increase in heart rate and force of ventricular contraction, or stroke volume (SV), attempts to increase the cardiac output (CO = HR × SV). If the cardiac output can be improved and/or vasoconstriction increases the systemic vascular resistance, the systolic blood pressure would increase (BP = CO × SVR). The adrenal medulla, which is the middle center portion of the adrenal gland that is located on the top of the kidney, is stimulated by the nervous system to release the hormones epinephrine and norepinephrine. The sympathetic nervous system also increases the respiratory rate.

Release of Hormones
While direct nerve stimulation occurs immediately, the hormones epinephrine and norepinephrine are released from the center portion of the kidneys within a few minutes. They exert a sustained sympathetic effect on the organs. Recall from Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and Chapter 8, “Pathophysiology,” that epinephrine stimulates alpha and beta receptors while norepinephrine mostly stimulates alpha receptors.

Alpha receptors are located primarily in vessel smooth muscle. When stimulated, the smooth muscle contracts, causing vasoconstriction. Thus, alpha stimulation results in vasoconstriction, which attempts to increase systemic vascular resistance and, in turn, blood pressure. The beta1 effect stimulates the heart and causes an increase in the heart rate and force of contraction. It also speeds the electrical impulse traveling through the conduction system of the heart, allowing for a faster heart rate. The heart rate and force of contraction are increased in an attempt to increase cardiac output. By increasing the cardiac output, the blood pressure may also be increased. The effects of alpha and beta receptor stimulation are summarized in Table 15-1.

In addition to epinephrine and norepinephrine, the body releases other hormones. Some of these hormones decrease urine output in an attempt to conserve body fluid through the reabsorption of water, while others cause further vasoconstriction, an increase in heart rate and contractility, and an increase in glucose in the blood. See Table 15-2.

Stimulation by the sympathetic nervous system and the release of hormones are geared to reversing the shock state and restoring the pressure in the arteries and perfusion to the cells. Many of the responses of the body to the stimulation of hormones produce the signs and symptoms seen in the shock patient.

Stages of Shock
As just discussed, the body attempts to compensate for disturbances in perfusion through the sympathetic nervous system and the release of hormones. The intention is to bring the dysfunction under control and restore the blood pressure and perfusion of tissues. There are three stages of shock: compensatory, decompensatory, and irreversible (Figure 15-9).
TRAUMA

Loss of blood volume from the vascular space decreases cardiac output and pressure in the aorta, carotid, and peripheral arteries.

Decrease in the delivery of oxygen and glucose to cells and the removal of carbon dioxide.

Baroreceptors trigger hormone release and sympathetic nervous system stimulation to increase cardiac output, blood pressure, and perfusion.

Patient becomes unresponsive, heart rate severely increases and then drops dramatically, blood pressure decreases significantly and may not be obtainable, respirations decrease and become inadequate.

Heart rate and contractility increase, vessels constrict, respiratory rate increases, and urine output decreases in an attempt to compensate and increase cardiac output, blood pressure, and perfusion.

Patient exhibits tachycardia, weak peripheral pulses, decreased mental status, tachypnea, and pale, cool and clammy skin.

Further decrease in blood volume, perfusion, and blood pressure leads to brain tissue death, multiple organ failure, and eventual patient death.

Brain becomes ischemic and medulla fails, causing a severe drop in perfusion and blood pressure.

Continued volume loss overwhelms compensatory mechanisms and blood pressure falls, tachycardia and tachypnea further increase, peripheral pulses are extremely weak or absent, mental status deteriorates.
and may also increase blood pressure (BP = CO × SVR). The respiratory system is stimulated to increase rate and tidal volume.

The sympathetic nerves also stimulate the adrenal medulla gland to release epinephrine and norepinephrine. The release of the hormones takes a few minutes; however, these hormones provide a sustained effect. The primary effects of epinephrine and norepinephrine are an increase in heart rate and contractility as well as vasoconstriction in an attempt to increase the blood pressure and perfusion. Vasoconstriction causes blood to be shunted away from nonessential areas, such as the skin and gastrointestinal tract, and to the core of the body to improve perfusion of the brain, heart, lungs, and other vital organs. An increase in the respiratory rate and tidal volume provides more oxygen in the alveoli for gas exchange. This coupled with an improvement in circulation is designed to deliver better oxygenated blood to the tissues.

Other hormones cause the kidneys to reabsorb sodium. In Chapter 8, "Pathophysiology," you learned that water follows sodium. Thus, as the kidneys reabsorb sodium, water is also reabsorbed within the body. Body fluid is conserved by decreasing urine output. However, the reduction in urine excretion also causes retention of waste products, which could increase the acidity of the blood.

This stage is referred to as “compensatory” because the body is able to compensate for the decrease in pressure. If the etiology of shock is reversed in this stage, for example, by stopping the hemorrhage, then the compensatory mechanisms will continue to maintain the blood pressure and perfusion and will eventually begin to signal the body to decrease its response as the pressure is restored.

The blood pressure may appear to be relatively normal in compensatory shock. However, you might also note a narrow pulse pressure. Recall that as the systolic blood pressure falls because of a decrease in cardiac output, the vessels constrict. This raises the diastolic blood pressure, which causes the systolic and diastolic values to come closer together.

As an example, if a patient is losing blood from a hemorrhage, as the cardiac output falls the systolic blood pressure reading decreases. The decrease in volume in the vessels causes a reduction in resistance and pressure inside the vessel. To compensate for the lowered pressure, the vessels constrict to increase resistance. By doing so, the pressure increases even though the volume inside the vessel is less. This may provide a deceiving picture of the normal perfusion and blood pressure. However, the narrow pulse pressure is an early sign of shock and provides important additional information about the cardiac output in relation to vasoconstriction.

This is an example of why you cannot rely on the presence or absence of only one sign when assessing for shock. You must at least assess mental status, blood pressure, pulse pressure, heart rate, and respiratory rate, as well as skin color, temperature, and condition.

### Decompensatory Shock

** Decompensatory shock, also commonly referred to as decompensated shock or progressive shock, ** is an advanced stage of shock in which the body’s compensatory mechanisms are no longer able to maintain a blood pressure and perfusion of the vital organs. If the shock state continues unopposed and is not managed effectively, the compensatory mechanisms become exhausted or overwhelmed, leading to a failure to maintain pressure inside the vessels and perfusion of the vital organs.

Cells, tissues, and organs become ischemic from a lack of perfusion and delivery of oxygen and glucose. Acid begins to build up in the blood from the anaerobic metabolism occurring in the cells. Heart function is depressed from the lack of adequate blood flow through the coronary arteries, leading to myocardial ischemia. Blood in the capillaries begins to sludge and form microemboli (small clots) as the capillaries become permeable from acid accumulation resulting from anaerobic metabolism, hypoxia, and lack of nutrients. The increased capillary permeability allows blood to leak out of the vessels and into the interstitial space, further lowering the vascular volume and pressure. A decrease in brain perfusion leads to cerebral ischemia. When the vasomotor center in the medulla becomes hypoxic it begins to fail, thereby reducing sympathetic nervous system stimulation, which allows vessels to dilate and cause a further drop in pressure and perfusion. This vicious cycle continues to breed more shock. Aggressive shock management may or may not reverse the process in the later stages of decomposition.

### Irreversible Shock

**Irreversible shock** is the stage in which, regardless of the intervention, the patient outcome is death. There are no definitive clinical signs indicating the transition from decompenosatory to irreversible shock. Cell, tissue, and organ failure and damage is so pervasive and severe that no matter what treatment is provided, organ death is inevitable and unable to be reversed. Microemboli begin to block capillaries throughout the body, leading to lung failure, kidney failure, and other multiple system organ failure (MSOF). Clotting factors are used in the formation of the microemboli in the blood. The body responds to the clots by releasing substances to attempt to break them up (fibrinolysis). Because the clotting factors were used up in the formation of the microemboli, the substances that are released to break down the clots are unopposed in the body and lead to widespread uncontrolled bleeding from any wound that was previously clotted, intra-venous catheter sites, mucus membranes, and the skin.

### Shock Assessment

Rapid identification of a shock state is imperative to effective management. Based on the stage of shock, the signs

and symptoms may be subtle or profound (Table 15-3). It is important in your assessment to consider history findings, physical assessment findings, signs of perfusion disturbance, and vital signs when attempting to recognize and identify shock. Do not rely on one finding, sign, or symptom. Consider the whole patient.

### History

Obtain a history from the patient. Pay particular attention to the chief complaint and any other associated signs or symptoms that might provide a clue to the etiology of the shock. Also gather information about the patient’s allergies, medications, past medical history, last oral intake, and events prior to the incident.

Pay particular attention to certain medications such as beta blockers and calcium channel blockers. Both of these types of medications keep the heart rate from dramatically increasing, making it appear that the patient is not in a compensatory stage of shock. As an example, a patient on beta blockers or calcium channel blockers may present with a heart rate of only 72 bpm while in a shock state. Without knowledge of the medication, one would consider this to be a normal finding and may be deceived from thinking the patient is in shock.

This is another example of why you should consider all of the assessment findings and not just one individually. In addition to the lowered heart rate, both beta blockers and calcium channel blockers may prevent the cardiac output from effectively responding during the compensatory stage, leading to a quicker deterioration in the patient’s condition. A patient on diuretics, which increase the urine output, may have less blood volume prior to the shock state and may deteriorate more rapidly.

### Physical Exam

During the primary and secondary assessment, assess for physical signs of shock and obtain vital signs. Be aware that the vital signs may appear somewhat normal, with only a slight increase in the heart rate and respiratory rate, when the patient is in compensatory shock and may deceive you into thinking that the patient is more stable than he really is. Thus, you must specifically assess signs
of perfusion as well as vital signs. (See Tables 15-4, 15-5, 15-6, and 15-7.) The signs of perfusion, independent of the vital signs, will provide evidence of a shock state. The following are signs of poor perfusion:

- Altered mental status
- Pale, cool, clammy skin
- Delayed capillary refill
- Decreased urine output
- Weak or absent peripheral pulses

In distributive shock, the skin is warm and flushed (red) from the vasodilation. After a period of time, the blood that has pooled in the extremities begins to deoxygenate and the skin becomes mottled. In cardiogenic shock, the skin appears to be pale, cool, and clammy early but takes on a cyanotic and mottled appearance as the shock state continues and the perfusion worsens.

Vital sign assessment must include the following:

- Blood pressure (both systolic and diastolic)
- Heart rate
- Pulse character
- Respiratory rate and tidal volume
- Skin color, temperature, and condition
- Pulse oximeter reading

The vital signs may vary, depending on the type of shock. Cardiogenic shock may present with an extremely slow heart rate or an irregular rhythm. Distributive shock from a spinal cord injury may present with a normal to slow heart rate and a blood pressure that is not extremely low. Both upper and lower airway compromise may be found in anaphylactic shock. These are only a few examples of variations of vital signs that might be found in the differing shock states.

Age Considerations in Shock

Age may influence the development, presentation, and management of shock, as well as recovery from shock. Shock states specific to pediatrics and geriatrics are discussed in Chapter 38, “Pediatrics,” and Chapter 39, “Geriatrics.” Briefly, elderly persons and newborns do not compensate well for shock. Thus, they have a tendency to deteriorate rapidly. Children and young adults compensate very well, often exhibiting only minor signs and symptoms for a long period of time and then decompensating suddenly. Normal vital sign findings vary with age for pediatric patients. For children less than 10 years of age, a systolic blood pressure of 70 mmHg plus two times the age in years is a lower limit of normal. A systolic blood pressure less than the lower limit would be considered hypotensive. Hypotension is a late finding in pediatric patients and often leads to cardiac arrest.

The geriatric patient does not compensate well for shock. In addition, the medications the elderly patient is taking may prevent some signs or symptoms from appearing, such as an elevated heart rate. An altered mental status and tachypnea may be the most profound signs of shock in the elderly.

General Goals of Prehospital Management of Shock

Management of shock is geared to improving oxygenation of the blood and delivery of oxygen and glucose to the cells. The general goals of shock management are:

- Secure and maintain a patent airway.
- Establish and maintain adequate ventilation.
- Establish and maintain adequate oxygenation via a nonrebreather mask at 15 lpm in the patient who is breathing adequately or supplemental oxygen delivered at the highest concentration via the ventilation device for the patient who is not breathing adequately.
- Do not hyperventilate the shock patient. Making the blood alkalotic from hyperventilation will reduce the off-loading of oxygen from the hemoglobin and promote further cellular hypoxia. Increasing the pressure inside the chest in a poor volume and perfusion state may further decrease preload and cardiac output.
- Stop the bleeding as quickly as possible using direct pressure. If direct pressure is not effective, proceed to application of a tourniquet. Consider hemostatic agents to control hemorrhage if permitted by your local protocol.
- Splint fractures to reduce bleeding; however, do not delay transport to perform individual splinting of fractures. Fracture management should be initially achieved with a long backboard and then continued en route if the patient’s condition and time allow.
- Do not remove an impaled object.
- Maintain the body temperature by removing wet clothing from water or blood, covering the patient to prevent further heat loss, and warming the patient compartment to 85 degrees for transport.
- Keep the patient in a supine position. Immobilize the patient to a backboard if a spinal cord or column injury is suspected.
- Apply the pneumatic antishock garment (PASG) if a pelvic fracture is suspected and the systolic BP is <90 mmHg, intraabdominal hemorrhage is suspected with severe hypotension, or retroperitoneal hemorrhage is suspected with hypotension. See Chapter 28, “Bleeding and Soft Tissue Trauma,” for more detailed information on the PASG.
- Rapidly transport the patient to the most appropriate medical facility.
- Consider ALS intercept for distributive, cardiogenic, obstructive, and nonhemorrhagic categories of shock. Follow your local protocol.
The normal electrical impulses are usually absent or disrupted or the mechanical response to the electrical impulse does not occur. Instead of smooth, coordinated contractions, the heart shows a different type of activity, most commonly the uncoordinated twitching known as ventricular fibrillation. Pumping action ceases and the body’s cells, without oxygenated blood, begin to die. Brain cells begin to die within 4 to 6 minutes following cardiac arrest. The patient presents as unresponsive and without a detectable pulse or spontaneous respiration.

Cardiac arrest patients are often described as having suffered sudden death, which occurs when the patient dies within 1 hour of the onset of the signs and symptoms.

**PATHOPHYSIOLOGY PEARLS**
Ventricular fibrillation is a chaotic and disorganized cardiac rhythm that causes the ventricles to quiver and does not produce ventricular contraction. No pulse or perfusion occurs during ventricular fibrillation.

**Pathophysiology of Cardiac Arrest**

Time is a critical issue in cardiac arrest. As time passes, the heart continues to deteriorate from a lack of oxygen and glucose and begins to undergo changes that lead to severe myocardial cell ischemia and eventually organ death. Unfortunately, the time is in minutes and begins immediately upon the onset of cardiac arrest. As soon as the patient goes into cardiac arrest, the resuscitation clock is ticking. The chance of a successful resuscitation decreases by 10 percent for every minute the patient is in ventricular fibrillation. If it is 5 minutes before someone finds the patient after he collapses and calls 911, and you have a 5-minute response time to get to the patient’s side, you are already 10 minutes into the cardiac arrest, which results in a less than favorable condition of the myocardium to begin resuscitative efforts. The brain is the most sensitive organ to cardiac arrest and, as previously noted, undergoes irreversible changes after 4 to 6 minutes.

There are three phases the patient goes through following cardiac arrest that lead to biological death: electrical phase, circulatory phase, and metabolic phase. Each phase is associated with variations in organ function and damage and has implications for emergency care.

**Electrical Phase**

The electrical phase begins immediately upon cardiac arrest and ends 4 minutes afterward. During this early and initial phase, the heart still has a good supply of oxygen and glucose; therefore, aerobic metabolism is maintained with continued energy production for cell function and prevention of mass production of acid. During this phase, the heart is in a good physiological condition for resuscitation. If CPR is started within these 4 minutes, the circulation of additional oxygen and glucose to the heart improves even further the chance of resuscitation, especially in the latter two phases. The primary issue during this phase in resuscitation is to restore an effective electrical rhythm to generate ventricular contractions that effectively eject blood and create an adequate cardiac output. Thus, during this phase, the heart is prepared for immediate defibrillation and restoration of the cardiac rhythm.

**Circulatory Phase**

The circulatory phase begins at 4 minutes and lasts through 10 minutes following the cardiac arrest. During this phase, the oxygen stores have been exhausted and the myocardial cells shift from aerobic to anaerobic metabolism. This results in very little energy production for cell function, in addition to the production of acid. The myocardial cells are becoming ischemic and are in need of oxygen and glucose. Because of the lack of oxygen and glucose, the heart is not prepared for defibrillation and is not prone to restarting. CPR will provide oxygen and glucose to the heart and improve the chance of a successful conversion following defibrillation. Thus, if the patient has been in cardiac arrest for 4 to 5 minutes or more and CPR is not being performed on your arrival, it is necessary to provide 2 minutes of CPR to deliver oxygen and glucose to the myocardial cells prior to any defibrillation to increase the chance of conversion to a perfusing rhythm.

**Metabolic Phase**

The metabolic phase begins 10 minutes after cardiac arrest. At this point the heart is starved of oxygen and glucose and has a large amount of acid buildup. The tissues are very ischemic and may begin to die. The chances of survival drop dramatically during this phase. Because of the lack of glucose and ATP, the sodium/potassium pump fails, allowing sodium to enter and stay within the cell. The sodium attracts water inside the cell. The cell swells and eventually ruptures and dies. This leads to the beginning of organ death. Resuscitation during this phase does not typically produce favorable results. If the patient is resuscitated, the widespread organ damage often leads to continued deterioration after restoration of the pulse and limited chances of the patient surviving or returning to a near normal level of neurological function.

**Terms Related to Resuscitation**

There are several terms related specifically to resuscitation of the cardiac arrest patient.

- **Downtime** is from the time the patient goes into cardiac arrest until CPR is effectively being performed.
- **Total downtime** is the total time from when the patient went into cardiac arrest until you delivered the patient to the emergency department.
- **Return of spontaneous circulation (ROSC)** is when the patient regains a spontaneous pulse during the resuscitation effort. The patient may not yet have
begun to breathe on his own; however, if the pulse returns spontaneously it is considered a ROSC.

- **Survival** in cardiac arrest is defined as a patient who survives to be discharged from the hospital. If a patient regained ROSC but later died in the hospital, it is not considered a survival.

- **Witnessed cardiac arrest** for the purposes of this chapter and the provision of resuscitation and defibrillation, is when the EMT witnesses the patient become unresponsive, apneic, and pulseless. It does not refer to a layperson watching the patient collapse.

- **Unwitnessed cardiac arrest** for the purposes of this chapter and the provision of resuscitation and defibrillation, is when the EMT arrives on the scene and the patient is already unresponsive, apneic, and pulseless.

### Withholding a Resuscitation Attempt

There are some situations in which you will not begin resuscitation on a patient in cardiac arrest. Some of these situations may include a patient with a valid do not resuscitate (DNR) order, physician orders for life-sustaining treatment (POLST), medical orders for life-sustaining treatment (MOLST), a patient with injuries that are not compatible with life such as a decapitation, and obvious death in patients who are in rigor and beyond the point of a resuscitation effort. Be sure to follow your local protocol when considering a decision to withhold resuscitation.

### The Chain of Survival

Successfully resuscitating a cardiac arrest patient in the prehospital setting can rarely be done solely with CPR. Success, instead, depends on a sequence of events that the American Heart Association has termed the chain of survival. There is a chain of survival for the adult and another for the pediatric patient. The adult chain of survival has five links:

**Adult Chain of Survival**

- **Immediate recognition and activation.** Time is a critical factor. The quicker someone can recognize a patient in cardiac arrest, begin chest compressions and CPR, and contact EMS the better the chance of survival. The two key factors are (1) recognition that a person who is unresponsive and has no breathing or no normal breathing has suffered a cardiac arrest, and (2) immediate activation of the EMS system. Immediate recognition can be achieved through public education programs, such as CPR courses for the layperson. Immediate activation of EMS is achieved by providing a simple access number, such as 911, to the community. In areas not serviced by 911, people must identify and call a seven- or ten-digit number to access EMS, which usually leads to time delays that may make the difference between successful resuscitation or not.

- **Early CPR.** Cardiopulmonary resuscitation (CPR), by providing coronary perfusion, significantly increases prehospital cardiac arrest survival rates. Research has shown that immediate CPR can double or even triple the chance of survival from ventricular-fibrillation-induced sudden cardiac arrest (VF SCA). This can be achieved through faster response by EMS and First Responders, more lay CPR providers, and EMS communications personnel providing CPR instructions to a person at the scene. Community CPR courses should aim to train as many people as possible. Recognition of a cardiac event and the proper access number should be emphasized as heavily as CPR skills. CPR should be initiated, beginning with chest compressions, immediately upon recognition of cardiac arrest. Minimize interruption of chest compressions.

- **Rapid defibrillation.** Defibrillation—but more important, early and rapid defibrillation (shock within minutes)—is another component in determining survival of cardiac arrest. Survival rates of patients in VF SCA decrease with every minute defibrillation is delayed. Defibrillation, the procedure of sending an electrical current through the chest, is necessary to convert an abnormal and lethal rhythm with no pulse to an organized rhythm capable of producing a pulse. The time from the onset of cardiac arrest to the time defibrillation is performed is the most essential factor in increasing prehospital cardiac arrest survival rates. Chest compressions should be initiated until the AED is available and applied. Minimize interruption of chest compressions during the AED application.

- **Effective advanced life support.** Advanced life support (ALS) is delivered most often by paramedics who can provide advanced cardiac life support (ACLS). In some systems, Advanced EMTs may be able to provide all or some ALS interventions.

- **Integrated post-cardiac-arrest care.** Once the heart is restarted, post-resuscitation care will focus on improving the patient’s chance to recover as nearly as possible to a normal neurological condition.

The American Heart Association pediatric chain of survival also has five links; however, the first three links emphasize slightly different elements of emergency cardiac care from those recommended for adults. This is based on the difference in the physiology and typical etiology of cardiac arrest in the pediatric patient.

**Pediatric Chain of Survival**

- **Prevention of arrest**
- **Early high-quality CPR performed by bystanders**
- **Rapid activation of EMS or other emergency medical responders**
- **Effective advanced life support and rapid transport to an appropriate medical facility**
- **Integrated post-cardiac-arrest care**

Even though the paramedic is able to perform all the functions of the EMT and also provide other advanced functions such as medication administration, tracheal tube placement, and cardiac pacing, it is important to
recognize that high-quality chest compressions and early defibrillation are the two single most critical factors to successful resuscitation. Both of these interventions, defibrillation and chest compressions, are well within the scope of practice for the EMT. The role of ALS is to perform certain interventions to increase the possibility of successful defibrillation or to administer medications to keep the patient from going back into cardiac arrest.

A system that has 911 or another easily recognizable public access number, CPR performed within minutes after the arrest by First Responders or laypersons, defibrillation within 4 minutes, and ALS capabilities will have better success rates for prehospital cardiac arrest patients.

### AUTOMATED EXTERNAL DEFIBRILLATION AND CARDIOPULMONARY RESUSCITATION

Early research from the American Heart Association (AHA) revealed that communities with early defibrillation programs—even those with no prehospital ACLS services—had improved survival rates of patients with cardiac arrest. It also verified that the earlier defibrillation took place, the better the outcome.

Ventricular fibrillation is the most common presenting rhythm in out-of-hospital sudden cardiac arrest. The AHA provides many reasons for the importance of delivering early defibrillation by EMS, which include the following:

- The most effective emergency care intervention to terminate ventricular fibrillation or ventricular tachycardia is defibrillation.
- The success of converting the cardiac rhythm from ventricular fibrillation or ventricular tachycardia depends on the delivery of effective CPR and defibrillation as early as possible following the onset of cardiac arrest. Interruptions when delivering chest compressions must be minimized to increase its effectiveness.
- Left untreated, ventricular fibrillation will quickly deteriorate to asystole, which carries a very low resuscitation success rate.

Research by AHA reinforces the necessity of early defibrillation in the management of VF SCA. However, high-quality CPR focusing on immediate chest compressions with minimal interruption was found to be even more important. Additional research shows that high-quality chest compressions with minimal interruption and early defibrillation are the greatest determinants of successful cardiac arrest management.

The AHA advocates “push hard and push fast” to provide effective chest compressions. Compressions delivered at a rate of at least 100/minute have been shown to provide suitable blood flow to essential organs during cardiac arrest. The AHA advocates a uniform compression-to-ventilation ratio of 30:2 for all patients (other than two-rescuer CPR for infants and children). The 30:2 ratio delivered over 1 minute will result in fewer breaths per minute overall, but in cardiac arrest, the patient’s need for oxygen is diminished (thus fewer breaths are needed).

Chest compressions should be initiated immediately upon confirmation of cardiac arrest. The AED should be readied and applied as soon as it is available during CPR to minimize interruption of compressions. When the defibrillation pads are applied and the AED is ready, chest compressions should be stopped immediately regardless of where the compressor and ventilator are in the cycle. Follow the AED prompts and defibrillate if advised. Immediately reinitiate chest compressions following defibrillation or if a no shock advisory is indicated and no pulse is palpated, minimizing compression interruption.

Pulse checks are not performed immediately after defibrillation because, although successful conversion from ventricular fibrillation occurs with the initial shock more than 85 percent of the time, it then takes several minutes for a perfusing rhythm to return. A pulse check immediately after defibrillation only lengthens the time until chest compressions resume, reducing the effectiveness of CPR and the chance of successful resuscitation. Thus, the most productive intervention following a defibrillation is to immediately resume CPR beginning with chest compressions for 2 minutes, then follow the AED prompts to reanalyze the rhythm and check the pulse if a no shock advisory is indicated.

When delivering CPR and automated defibrillation to sudden cardiac arrest patients, the AHA emphasizes the following:

- When performing chest compressions “push hard and push fast” to maximize the pressures needed for blood circulation.
- Deliver compressions at a rate of 30 compressions to 2 ventilations to minimize the interruption of chest compressions.
- Following defibrillation, immediately resume CPR with chest compressions without a pulse check to reduce the interruption in the delivery of chest compressions.
- Deliver the minimum rate and volume of artificial ventilation to minimize the negative effect on perfusion pressures.

### Types of Defibrillators

A defibrillator, as alluded to up to this point, is a device that will deliver an electric shock to convert a fibrillating heart to an organized rhythm with a pulse. External defibrillators used in emergency care are called “external” because they are applied to the outside of the chest.
There are two basic categories of external defibrillators: manual and automated. The use of manual defibrillators requires extensive training, and they are used by qualified ALS providers. The operator uses the machine’s monitor to determine the heart’s rhythm as displayed on a screen. The operator must analyze the rhythm and decide whether it is appropriate to defibrillate. He must apply the defibrillator pad or gel, hold the paddles firmly against the patient’s chest (or attach large defibrillation pads to the chest wall), and administer the shock. Automated external defibrillators are much simpler to operate. This has made possible a broader use of defibrillation.

With AEDs, external adhesive defibrillator pads are attached to the patient’s chest. Those pads are connected by cables to the AED. The pads transmit the patient’s cardiac rhythm to the AED’s circuitry, where the rhythm is analyzed. If the AED determines that an electrical shock (defibrillation) is appropriate, the device delivers the shock through the cables via the pads to the patient.

**Advantages of AEDs**

With the AED, the device analyzes the rhythm and indicates if a shock is required. The AED operator need only recognize that the patient is in cardiac arrest and understand the steps in operating the device. Therefore, initial training and continuing education are much simpler with AEDs than with manual defibrillators.

There are several other advantages of the AED:

- **Speed of operation.** The first shock can be delivered to the patient within 1 minute of the AED’s application at the patient’s side. Clinical trials conducted by the AHA found that operators of AEDs can consistently deliver a first shock more quickly than operators of manual defibrillators.

- **Safer, more effective delivery.** Because it uses adhesive external pads, instead of the paddles that must be held against the chest during manual defibrillation, the AED allows for “hands-free” defibrillation, which is safer for EMS personnel. In addition, the adhesive pads cover a larger surface area than the manual paddles and, therefore, deliver a more effective shock.

- **More efficient monitoring.** AEDs are manufactured with sensors that detect loose leads and false or misleading rhythm readings. The large electrodes make better contact with the patient’s body and provide a better ECG tracing, even when the patient is severely diaphoretic (sweaty).

**Types of AEDs**

In general, there are two types of AEDs:

- **Fully automated AEDs.** The fully automated AED is completely automatic. The operator determines that the patient is in cardiac arrest, attaches the device to the patient, and pushes a button to turn on the power. The device does the rest. The fully automated AED analyzes the heart rhythm and determines whether ventricular fibrillation is present. If ventricular fibrillation is detected, the AED charges automatically and delivers the appropriate electrical shock. Semi-automated AEDs are preferred, however, fully automated models are still available and possibly in use by laypersons and some First Responders.

- **Semiautomated AEDs.** The semi-automated AED requires more involvement by the operator. The operator attaches the AED to the patient in the normal manner, pushes a button to turn on the power, and initiates the heart rhythm analysis. Some models may require the operator to push an analysis button as well. The AED then begins the analysis. When the analysis is complete, a computer voice synthesizer and/or display message indicates to the operator when a shock is advised. The operator must then push another button to deliver the shock. Some devices also provide a display of the heart rhythm as it is being analyzed.

AEDs are often equipped with a variety of features that can provide a record of both the operator’s use of the device and the AED’s own functions. Such devices include voice and ECG recorders and memory modules.

Some external defibrillators use the older monophasic waveform. Most now use the newer biphasic waveform (Figures 15-10a to 15-10d). The monophasic AED delivers the energy at 200, 300, and 360 joules in one direction. The biphasic delivers lower energy (typically less than or equal to 150–200 joules) pulses. The lower energy delivered by the biphasic AED is thought to cause less heart cell damage, yet is still more effective at terminating ventricular fibrillation.

Whichever type of AED your service uses, always follow the manufacturer’s directions and service recommendations as well as any local protocols for AED use.

**Analysis of Cardiac Rhythms**

The main component of the AED is the computer microprocessor that records and analyzes whether a heart rhythm should be defibrillated. The rhythms for which defibrillation is appropriate are these:

- **Ventricular fibrillation.** As noted earlier, **ventricular fibrillation (VF or V-Fib)** is a disorganized cardiac rhythm that produces no pulse or cardiac output (Figure 15-11a). It is commonly associated with advanced coronary artery disease, though it may have other causes. Somewhere between 50 and 60 percent of cardiac arrests will be in ventricular fibrillation during the first 8 minutes after becoming pulseless. V-Fib is most commonly the rhythm that the AED defibrillates.

- **Ventricular tachycardia.** **Ventricular tachycardia (VT or V-Tach)** is a very fast heart rhythm (Figure 15-11b).
That is generated in the ventricle instead of the sinoatrial node in the atrium. Because the pumping is so rapid, the heart does not refill properly and cardiac output is sharply reduced. This rhythm can easily degenerate into ventricular fibrillation. The AED will respond to V-Tach, usually when the heart rate exceeds 180 beats per minute. However, you should be aware that some V-Tach patients remain responsive; since they are not pulseless, they are not appropriate candidates for defibrillation. The AED should ONLY be applied to patients who are pulseless, not breathing (apneic) or have agonal respirations, and unresponsive.

The AED will detect rhythms for which no shock is indicated. They include the following:

- **Asystole.** Asystole is the absence of electrical activity and pumping action in the heart. This often registers on a monitoring screen as a flat or nearly flat line; hence the term “flatline” is often used for asystole (Figure 15-11c). There is no cardiac output or pulse. Chances of recovery from asystole are not good. Defibrillation is not appropriate in asystole.

- **Pulseless electrical activity.** In cases of pulseless electrical activity (PEA), the heart has an organized rhythm, but either the heart muscle is so weakened that it fails to pump, or the heart muscle does not respond to the electrical activity, or the circulatory system has lost so much blood that there is nothing to pump. Defibrillation is not appropriate in these rhythms.

  Note that the AED is a very sensitive instrument. It can sense spontaneous patient movement, movement of the patient by others, engine vibrations if the patient is in a vehicle, and even some radio transmissions. Such “noise” interferes with the AED’s analysis of the patient’s heart rhythms.

  For these reasons, no one should be touching the patient when the AED is analyzing the rhythm. (Nor should anyone be touching the patient during administration of AED shocks.) Always alert people to move away from the patient by saying “Clear!” in a loud voice before
beginning the analysis and be sure to look around to verify visually that no one is in contact with the patient. A properly maintained and operated AED will not deliver inappropriate shocks, but human error can lead to them. Human error occurs when an operator misinterprets a patient’s condition, and applies the AED to someone not in cardiac arrest. If the patient has an extremely rapid heart rate, the AED may defibrillate the rhythm.

**When and When Not to Use the AED**

The AED was initially developed for adults. However, the 2010 AHA guidelines indicate it can be used with any age, even those less than 1 year of age. However, manual defibrillation is preferred for patients less than 1 year old to better control the amount of energy delivered. If the patient is between 1 and 8 years of age, an adult AED can be used, preferably with a dose attenuating system to reduce the defibrillation energy being delivered to the child (Figure 15-12). If no dose-attenuating
system is available, proceed with the regular adult pads and defibrillation.

Apply the adult AED without the dose-attenuating system in any patient over 8 years of age. In either group of patients, immediately begin chest compressions and apply the AED as soon as it becomes available. During application of the electrode pads, continue chest compressions until the AED is completely ready for analysis of the patient rhythm. Once applied, immediately proceed with the AED protocol. The goal is to deliver the defibrillation within 5 minutes from the onset of ventricular fibrillation.

As mentioned previously, the AED is intended for nontraumatic cardiac arrest patients. These patients must be unresponsive, with no breathing or agonal breathing, no signs of life, and no pulse. The AED is not intended for trauma patients. In trauma patients, cardiac arrest is more likely to have resulted from the trauma than from an underlying cardiac cause. If such patients are in cardiac arrest, the condition often is the result of blood loss. Defibrillation usually will not help these patients. Follow local protocols and contact medical direction if in doubt. If a trauma patient is in cardiac arrest, begin CPR and perform bleeding control and spinal immobilization and apply the AED according to your local protocol.

You may come across situations where you cannot tell if the trauma led to cardiac arrest or vice versa. Suppose, for example, that you discover a man in cardiac arrest in a car that has gone off the road and hit a tree. Did the man go into cardiac arrest while driving, then swerve off and hit the tree? Or did he drive off the road for some other reason and go into cardiac arrest only after hitting the tree and sustaining other injuries? In such cases, err to benefit the patient and immediately initiate CPR and apply the AED as soon as it is available. Follow local protocols to determine when use of the AED is appropriate.

**RECOGNIZING AND TREATING CARDIAC ARREST**

Now that you have reviewed abnormal rhythms, basic information about defibrillation, and the AED, you can learn the procedure for defibrillation.

**Assessment-Based Approach: Cardiac Arrest**

Dispatch may provide information that will lead you to suspect cardiac arrest. Reports that a patient doesn’t appear to be breathing, is unresponsive, or that First Responders are performing CPR clearly indicate cardiac arrest. But be alert to the possibility of cardiac arrest in calls to patients with chest pain or discomfort, difficulty in breathing, or seizures. Although not all chest pain patients will go into cardiac arrest and need CPR and the AED, patients with cardiac compromise can rapidly deteriorate to cardiac arrest. Some patients will suffer a brief seizure immediately after going into cardiac arrest. Bring the AED from the ambulance to the patient on such calls.

**Scene Size-Up and Primary Assessment**

On arrival, take appropriate Standard Precautions. Ensure that the scene is secure. Then proceed rapidly with the primary assessment.

Form a general impression of the patient and his mental status as you approach. If the suspected cardiac patient is responsive, follow the procedures for assessment and care described earlier for cardiac-related emergencies.

In an unresponsive patient who appears to have no signs of life, quickly assess for apnea or agonal ventilations while simultaneously checking a carotid pulse (a brachial pulse in pediatric patients less than 1 year of age). Assess for no longer than 10 seconds. If the patient is unresponsive, is apneic or has agonal ventilations and appears to have no other signs of life, immediately begin CPR using the CAB intervention sequence outlined in the 2010 AHA guidelines. CAB stands for chest compressions, airway, and ventilation. This sequence requires the EMT to immediately initiate CPR beginning with 30 chest compressions followed by opening the airway and 2 ventilations. If multiple EMTs are on the scene, many of the interventions can be accomplished simultaneously, such as preparing the AED, inserting an airway, and readying the bag-valve mask for ventilation while the first 30 compressions are being performed. The key is to initiate chest compressions as the first intervention, minimize any interruption in chest compressions during the entire resuscitation, and apply the AED as quickly as possible. Once you have determined that a patient is in cardiac arrest, proceed with CPR while you prepare to deliver emergency care as described next.

- **Patients under 1 year of age (infants).** For pediatric patients less than 1 year of age, use the CAB intervention approach to CPR and resuscitation. A ratio of 30 compressions:2 ventilations is used when one EMT is performing CPR; however, a ratio of 15 compressions:2 ventilations is used when two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute. The compression depth should be one-third the anterior-posterior chest diameter or approximately ½ inches or 4 cm. Because most cardiac arrests in this age group occur from an airway, oxygenation, or ventilation issue, ensure you have an open airway, are providing good ventilations, and are adequately oxygenating the patient. Apply the AED as soon as it is available. Use a pediatric dose-attenuating system if possible. If manual defibrillation or a pediatric dose-attenuating
system is not available, proceed with the use of the adult AED. Follow your local protocol.

If the heart rate is >60/minute and ventilations are absent or inadequate, immediately begin positive pressure ventilation at 12–20/minute (1 ventilation every 3 to 5 seconds). If the heart rate is <60/minute with signs of poor perfusion (pallor, mottling, cyanosis) after ventilation and oxygenation have been delivered, initiate CPR beginning with chest compressions.

**Patients 1–8 years of age.** For pediatric patients between 1 and 8 years of age, use the CAB intervention approach to CPR and resuscitation. A ratio of 30 compressions:2 ventilations is used when one EMT is performing CPR; however, a ratio of 15 compressions:2 ventilations is used when two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute. The compression depth should be one-third the anterior-posterior chest diameter or approximately 2 inches or 5 cm. Because most cardiac arrests in this age group occur from an airway, oxygenation, or ventilation issue, ensure you have an open airway, are providing good ventilations, and are adequately oxygenating the patient. Apply the AED as soon as it is available. It is preferred that defibrillation be done using a pediatric dose-attenuating system. If a pediatric dose-attenuating system is not available, proceed with the use of the adult AED. Follow your local protocol.

If the heart rate is >60/minute and the ventilations are absent or inadequate, immediately begin positive pressure ventilation at 12–20/minute (1 ventilation every 3 to 5 seconds). If the heart rate is <60/minute with signs of poor perfusion (pallor, mottling, cyanosis) after ventilation and oxygenation have been delivered, initiate CPR beginning with chest compressions.

**Patients over 8 years of age.** Adult interventions are used for patients over 8 years of age. If the cardiac arrest was witnessed, immediately initiate CPR beginning with chest compressions (CAB intervention sequence). As soon as the AED is available, apply it while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with the AED protocol.

A ratio of 30 compressions:2 ventilations is used when one or two EMTs are performing CPR. Chest compressions should be delivered at a rate of at least 100/minute. The compression depth should be at least 2 inches or 5 cm.

When performing CPR on a patient who is obviously pregnant or in her third trimester, use a manual maneuver to displace the uterus laterally while the patient is supine. Use your hand(s) to push the uterus to one side. If not successful, tilt the patient no more than 30 degrees by placing padding under the right side of the backpack.

---

**Secondary Assessment**

While CPR is being done and the AED is being set up and applied, an EMT may be able to gather the history from bystanders or relatives. Do not delay defibrillation or interrupt chest compressions to obtain the history.

**Signs and Symptoms.** The signs and symptoms of cardiac arrest are as follows:

- Unresponsive
- No breathing (apnea) or no normal breathing (gasping type agonal ventilations)
- No pulse (should be checked simultaneously with breathing and for less than 10 seconds)
- No other signs of life

**Emergency Medical Care**

Follow the steps listed under “Performing Defibrillation” to provide emergency medical care with an AED to cardiac arrest patients. Remember to use CPR and defibrillation as appropriate for arrest patients according to their age. Managing a patient in cardiac arrest is one of the most dynamic situations the EMT will be in, necessitating almost all the skills you acquire during your education.

**Reassessment**

CPR and, as needed, defibrillation will be performed to restore the patient’s pulse and perfusion. Once the pulse is restored, you will continue to perform reassessments en route to the hospital. As will be discussed in the following segment, a patient whose pulse has been restored may revert into cardiac arrest, so the reassessment will be focused especially on monitoring the patient’s pulse, breathing, and mental status.

**Performing Defibrillation**

Ideally, at least two EMTs should be available when the AED is to be used, one to operate the device and provide ventilation and the other to perform good chest compressions with minimal interruption (Figure 15-13 ■).

**Using an AED**

The steps that follow are for providing defibrillation with a semiautomated AED.

Note that the most recent semiautomated AED typically has two buttons. Button number 1 turns on the power and starts analysis of the patient’s heart rhythms; button number 2 delivers the defibrillation. Visualize these two buttons as you read the following steps. Some older semiautomated AEDs have three buttons to turn the device on, start the rhythm analysis, and deliver the defibrillation.
Bear in mind, as you read the following steps (see also EMT Skills 15-1A to H), that you should deliver only one shock before intervening with five cycles of CPR, which is approximately 2 minutes in duration.

1. **Take Standard Precautions.** This should normally be done en route to the scene.

2. **Perform a brief primary assessment of the patient** (EMT Skills 15-1A). If the patient is unresponsive, is apneic or has agonal ventilation, has no pulse (checked simultaneously with ventilation and for no more than 10 seconds), and has no other signs of life, immediately initiate CPR beginning with chest compressions (CAB intervention sequence)—whether the arrest was witnessed or unwitnessed. As soon as the AED is available, apply it while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with the AED protocol.

   If bystanders or First Responders are already performing CPR upon your arrival, instruct them to continue while you prepare application of the AED.

3. **Continue chest compressions while the AED is readied for operation** (EMT Skills 15-1B). If possible, perform AED operations from the patient’s side to minimize any interruption in chest compressions.

4. **Turn on power to the AED** (EMT Skills 15-1C).

5. **Continue chest compressions while attaching the adhesive monitoring defibrillation pads** (EMT Skills 15-1D). Minimize any interruption to chest compressions.

6. **Follow the manufacturer’s instructions for applying the pads, turning on power, and pad placement.**

7. **Begin analysis of the patient’s cardiac rhythm** (EMT Skills 15-1E). The AED will automatically monitor and analyze the rhythm and will indicate the start of analysis mode by prompting you to clear the patient, stop any ongoing chest compressions or ventilation, and say “Clear!” making sure that no one is touching the patient. The AED cannot effectively analyze the cardiac rhythm while chest compressions or ventilation is being performed. Also, anyone in contact with the patient during delivery of a shock could be injured. Finally, minimize any interruption of chest compressions each time the AED analyzes and delivers a shock.

8. If the AED’s analysis determines a shock is appropriate, it provides a “deliver shock” message. In that case, proceed with defibrillation by depressing the shock or defibrillation button (EMT Skills 15-1F). If the AED’s analysis determines a nonshockable rhythm, it gives a “no shock” message. In that case, immediately resume CPR beginning with chest compressions.

9. **After a shock has been delivered, immediately resume CPR beginning with chest compressions.** Perform CPR for approximately 2 minutes (EMT Skills 15-1G).

10. **After 2 minutes, the AED reanalyzes the rhythm.** If a shock is indicated, proceed with defibrillation, then immediately resume CPR beginning with chest compressions. If there is a prompt to check breathing and pulse, quickly assess the patient’s breathing and carotid pulse (EMT Skills 15-1H). (Check a brachial pulse in the pediatric patient <1 year of age.)

    The AED may indicate the patient now has a pulse or no longer has a shockable rhythm. If the patient is unresponsive, apneic or has agonal ventilations, and has no pulse, immediately resume CPR beginning with chest compressions. Continue to repeat this sequence. If the patient has a pulse, continue with ventilation at 10 to 12/minute or one ventilation every 5 to 6 seconds in the adult and 12 to 20/minute or one ventilation every 3 to 5 seconds in the pediatric patient (<8 years of age). Continuously reassess the patient.

11. **Follow your local protocol regarding when to transport the patient in cardiac arrest.**

---

**Use of the AED by a Single EMT**

There are times when only a single EMT is initially available to provide emergency care for a cardiac arrest...
patient. If the EMT has access to an AED and the patient’s profile meets the inclusion criteria for AED usage, he should follow this sequence:

1. Verify that the patient is unresponsive, with no breathing and no pulse.
2. Call for additional EMS and get the AED.
3. Immediately apply the AED and proceed with the AED protocol.

Fully automated AEDs may be used by some emergency responders or found in public facilities.

Transporting the Cardiac Arrest Patient

If you have followed the emergency medical care procedures and operation of the AED as just described and no ALS backup is responding to the scene, you should transport the patient when any one of the following conditions applies:

- The patient regains a pulse.
- Your local protocol indicates transport after a prescribed number of shocks or no shock indicated messages. Some protocols recommend transport after the administration of the third defibrillation or three consecutive no shock indicated messages are received.

The patient you transport after defibrillation will be in one of two conditions: with a pulse or without a pulse.

Transporting a Patient with a Pulse

If a patient’s pulse has returned after defibrillation:

1. Check the patient’s airway and provide oxygen at 15 lpm by nonrebreather mask if the patient’s breathing is adequate, or provide positive pressure ventilation with supplemental oxygen if the patient’s breathing is inadequate.
2. Since many cardiac arrest patients vomit, have suction ready for use and clear the airway of any obstructions or fluids.
3. Secure the patient to a stretcher and transfer him to the ambulance. If you regained a pulse while still on scene, the patient should be placed on a backboard so that compressions will be more effective if the cardiac arrest recurs en route to the medical facility.
4. Consider the most efficient way of getting ACLS to the patient. Consult with dispatch and medical direction and consider rendezvousing with an ALS unit en route or awaiting arrival of the ALS unit if that will get the patient advanced care more rapidly.
5. Continue to keep the AED attached to the patient during transport.
6. If you have not already done so, perform the secondary assessment en route.
7. Perform reassessment every 5 minutes.

Patients who have been brought out of ventricular fibrillation through use of the AED have a high likelihood of deteriorating back into that state. Monitor these patients closely. With unresponsive patients, check the pulse every 30 seconds. Therapeutic hypothermia is a common practice in the cardiac arrest patient with a return of spontaneous circulation (ROSC). Follow your local protocol.

If the patient returns to cardiac arrest, follow the AED prompts. If no shock is advised, immediately initiate CPR beginning with chest compressions. If a shock is advised, deliver the shock safely and immediately initiate CPR beginning with chest compressions. Follow the AED protocol.

Transporting a Patient Without a Pulse

If the patient has no pulse, continue to provide CPR and defibrillation and follow local protocol. Use extreme caution and safety precautions when defibrillating a patient in the back of the ambulance to avoid accidental shocks to EMTs. Rendezvous with ALS as early as possible.

Providing for Advanced Cardiac Life Support

As an EMT, you can operate an AED without advanced life support personnel on scene. With cases of cardiac arrest, however, you should keep the AHA’s chain of survival in mind. The fourth link of that chain is effective advanced cardiac life support (ACLS).

There are often several options for obtaining ACLS for a patient. Higher-level EMS providers, such as paramedics and some Advanced EMTs, can provide it. If prehospital personnel are not available, other sources for ACLS might be a hospital or clinic.

Whenever you have a cardiac arrest patient, follow your protocol, which may include informing medical direction and requesting ACLS backup as possible. Your system will have protocols about the transport of such patients, but medical direction, or your protocol, depending on the circumstances, may tell you to wait for the arrival of the ALS team, to rendezvous with them en route, or to proceed directly to a hospital or other facility. The goal is to minimize the time from the delivery of CPR and defibrillation to the arrival of ACLS.

Summary: Assessment and Care

To review assessment findings that may be associated with cardiac arrest and emergency care for cardiac arrest, see Figures 15-14 and 15-15.
Assessment Summary

**CARDIAC ARREST**
The following are findings that indicate cardiac arrest. These findings are obtained during the primary assessment:
- Unresponsive
- Apneic (not breathing)
- Pulseless

Emergency Care Protocol

**CARDIAC ARREST**
1. Take Standard Precautions.
2. Perform a brief primary assessment of the patient. If the patient is unresponsive, apneic or has agonal ventilation, has no pulse (checked simultaneously with ventilation and for no more than 10 seconds), and no other signs of life, immediately initiate CPR beginning with chest compressions.
3. Immediately initiate CPR beginning with chest compressions (CAB intervention sequence). As soon as the AED is available, apply it while chest compressions are being performed. When the AED is ready to start the rhythm analysis, stop chest compressions and proceed with AED protocol.
   If bystanders or First Responders are already performing CPR when you arrive, instruct them to continue while you prepare application of the AED.
4. Continue with chest compressions while the AED is readied for operation.
5. Turn on power to the AED.
6. Attach the adhesive monitoring-defibrillation pads to the chest while chest compressions are being performed. Minimize any interruption to chest compressions.
8. If the AED’s analysis indicates a shock, it provides a “deliver shock” message. In that case, proceed with defibrillation by depressing the shock or defibrillation button. If the AED’s analysis determines a nonshockable rhythm, it gives a “no shock” message. In that case, immediately resume CPR beginning with chest compressions.
9. After a shock has been delivered, immediately resume CPR beginning with chest compressions. Perform CPR for approximately 2 minutes.
10. After 2 minutes, the AED reanalyzes the rhythm. If a shock is indicated, proceed with the defibrillation, then immediately resume CPR beginning with chest compressions. If the AED gives a prompt to check breathing and pulse, quickly assess the patient’s breathing and pulse. The AED may indicate the patient now has a pulse or no longer has a shockable rhythm. If the patient is unresponsive, apneic or has agonal ventilations, and has no pulse, immediately resume CPR beginning with chest compressions. Continue to repeat this sequence. If the patient has a pulse, continue with ventilation. Continuously reassess the patient.
11. Follow your local protocol regarding when to transport the patient in cardiac arrest.

SPECIAL CONSIDERATIONS FOR THE AED

Safety Considerations
When you are using an AED, you are operating a device that delivers an electric shock. That shock can save the life of a cardiac arrest patient, but it can injure others who come in contact with it. Such shocks are unlikely to be lethal, but they should be avoided.

Electricity can be conducted, or carried, through a variety of different substances. The human body is one of them. No one should be in contact with the patient during the AED’s rhythm analysis or its delivery of defibrillating shocks. Remember to say loudly, “I’m clear, you’re clear, everyone’s clear!” and to make sure that everyone is, in fact, clear of the patient before beginning the analysis or defibrillating.

Water is an excellent conductor of electricity. The AED should not be operated if the machine or the patient is lying in water, the chest is covered with water, or the patient is extremely diaphoretic. If the patient is lying in water, it may be necessary to move the patient to a dry and safe area before using the AED. You must
Emergency Care Algorithm

Unresponsive, apneic, or agonal ventilation and pulseless

Yes

Immediately initiate CPR beginning with chest compressions

Blue = interventions

also dry the patient’s chest if wet or excessively diaphoretic before delivering a shock or the energy may arc between the electrodes. The AED can be used safely if the patient is lying on snow or ice.

Metal is another good conductor of electricity. Be careful with patients on metal flooring, catwalks, stretchers, and other items with metal components. Ensure that no one else is directly in contact with metal that is touching the patient before you administer a shock.

If a patient has a transdermal medication patch on his chest (such as nitroglycerin, nicotine, or analgesics), remove it quickly while wearing gloves and wipe the site with a towel or gauze pad before applying the defibrillator pad. Minimize the delay to defibrillation and interruption of chest compressions when doing so. Do not place AED pads over the medication patch. The patch may reduce the effectiveness of the shock by blocking the energy or may cause burns to the skin. (The shock may cause the plastic in the patch to melt and ignite.) Be sure to wipe the nitroglycerin completely from the skin prior to defibrillation.

An extremely hairy chest, another problem that may be encountered, is not necessarily a safety issue but rather an effectiveness issue. If the patient has a very hairy chest, it is possible that the electrodes will stick to the hair and not the skin. This will reduce the amount of energy delivered to the patient and may cause the AED to continuously prompt you to “check the electrodes” for failure of good contact. If you should receive a “check electrodes” message after applying the AED, you can attempt to correct the problem by trying one of the following steps:

- Firmly press down on the pad in an attempt to stick it to the chest wall skin.
- If this does not work, pull the original set of electrodes off. This will remove some of the hair in the area. Apply a second, new set of electrodes with firm pressure applied to the pad.
- If the AED continues to give you a “check electrode” message, consider clipping chest hair with scissors or shaving the area with a disposable razor. Then apply a third, new set of electrode pads.

Keep several extra sets of electrodes and razors in the AED case. Without good contact between the electrodes and the chest, the defibrillation may not be effective or the AED will not allow the energy to be discharged. Be sure to minimize the delay to defibrillation and interruption of chest compressions when doing so.

**AED Maintenance**

Scheduled maintenance of the AED is crucial to ensuring that the machine functions properly. Follow your local protocols and the manufacturer’s directions when maintaining the AED.

You should be aware that AED failure is most commonly attributed to improper maintenance, especially battery failure. Operators of the AED must ensure that batteries are properly maintained and replaced on a set schedule to guarantee proper energy levels. The AED, its batteries, and the system self-check status indicator should be checked at the beginning of each shift. Extra, fully charged batteries should always be available.

**Training and Skills Maintenance**

In addition to ensuring that the AED functions properly when needed, EMTs must also ensure that they can use the device properly when called on to do so. This can be accomplished through continuing education and skills maintenance programs. One recommendation is that an AED operator should refresh or practice his skills with the device every 90 days.

Operators should review incidents of AED use in the system, study any new protocols, and, most importantly, practice working with the system’s device. More information regarding updated research on AED procedures can be obtained from several sources, including EMS journals, state EMS offices, and the AHA.

**Medical Direction and the AED**

Medical direction must play a significant role in the provision of AED services. EMTs use AEDs under the authority of the medical director’s license. Medical direction thus has a great stake in ensuring that a system’s AED program functions properly. Medical direction’s involvement might include the following:

- Making sure that the EMS system has all necessary links in the AHA Chain of Survival
- Overseeing all levels of EMTs
- Reviewing the continual competency skill review program
- Engaging in an audit and/or quality improvement program

As part of the quality review and improvement program, the system’s medical director or a designated representative should review all incidents of AED use. Such reviews can reveal steps that might be taken to speed the entry of cardiac arrest patients into the system, to improve AED training, or to coordinate more effectively AED operation with ACLS backup. These reviews may be accomplished through the following:

- Written reports
- Review data provided by the AED

**Energy Levels of Defibrillators**

Defibrillators, semiautomated or manual, deliver electrical current to the heart through the chest wall. Electrical current for defibrillators is measured in units called joules. Manual monophasic waveform defibrillators can deliver a range of current levels, usually from 5 or 10 joules to
360 joules. Most monophasic AEDs have two preset values of 200 and 360 joules programmed into the machine. Biphasic waveform defibrillators use lower energy settings for defibrillators, typically 150–200 joules for a biphasic truncated exponential waveform or 120 joules with a rectilinear biphasic waveform. It is not so important that EMTs know the difference between a “truncated exponential” and “rectilinear biphasic” waveform machine, rather that they deliver the appropriate amount of energy for their type of AED in a time-efficient and safe manner.

### Cardiac Pacemakers

People whose conduction system cannot sustain a regular and effective rhythm on its own often receive surgically implanted cardiac pacemakers. These devices, powered by long-life batteries, are placed under the skin and have tiny electrodes connecting to the heart. Whenever the patient’s heart rate moves outside a certain range, the device takes over the task of setting the heart’s pace.

Cardiac pacemakers are usually positioned beneath one of the clavicles. They form a visible lump and can be palpated (Figure 15-16a and 15-16b). If you detect a pacemaker in a cardiac arrest patient, you can still use the AED. However, be sure not to place an adhesive pad directly over the pacemaker.

### Automatic Implantable Cardioverter Defibrillators

As an EMT, you may encounter automatic implantable cardioverter defibrillators (ICDs) in some patients. These devices are surgically implanted and used in cases of ventricular heart rhythm disturbances that cannot be controlled by medication. The ICD is able to monitor the heart’s electrical activity and provide a shock to the heart if it detects a shockable dysrhythmia. Usually the device will deliver four to five shocks. If a patient with an ICD is responsive, he will be able to tell you if he has an ICD and when it is delivering a shock.

If you encounter a responsive cardiac patient with an ICD, allow the device to operate, stabilize the patient, and prepare him for transport. With unresponsive cardiac patients, look for surgical scars on the chest or left upper quadrant of the abdomen. Also look for medical identification tags. Treatment for the unresponsive patient with an ICD is the same as for any other unresponsive cardiac patient. However, when applying the AED’s adhesive pads in such patients, do not place them directly over the implanted ICD because the device has an insulated backing that will deflect the shock. Place the electrode pad 1 inch to the side of the ICD, or use an electrode positioning arrangement that avoids the ICD (either the anterolateral or anterior–posterior, arrangement). If the ICD is delivering shocks (indicated by the contraction of the patient’s muscles), wait 30 to 60 seconds for the ICD to complete its cycle prior to attaching the AED, because the AED and ICD analysis and shock cycles may conflict. There have been no reported injuries from contact with ICD patients while the device is delivering a shock. However, a slight tingling sensation may be detectable. Wearing exam gloves may prevent this.

### Automated Chest Compression Devices

The efficiency of blood flow in cardiac arrest when external chest compressions are being delivered is a
function of how well the chest wall surrounding the heart is being compressed. Even under ideal situations of CPR skill performance, the quality of blood flow from externally applied chest compressions does not parallel normal cardiac output. In addition, CPR efficiency is also hampered by rescuer fatigue, the type of surface the patient is lying on when compressions are being delivered, and the accuracy with which the provider is delivering the compressions (i.e., maintaining good depth, rate, and sequence). When resuscitating a patient, chest compressions require that at least one EMT perform chest compressions. This means that person cannot help ventilate the patient or even help move the patient since that EMT should be doing continuous compressions. Ideally the EMT performing chest compressions would be relieved after every 2 minutes to ensure good chest compressions.

Numerous devices to help deliver external compressions to the patient have been developed in an attempt to improve circulation associated with the compressions. These devices not only allow for increased uniformity in skill provision, but also free up a provider to assist with other patient care tasks. There are many mechanical compression devices still in the research and development stage, waiting to receive federal approval for use in the United States or that have not yet been recommended by the American Heart Association for use in the arrested patient. The efficacy of these devices has not yet been proven.

**Mechanical Piston Device**

The mechanical piston device is an apparatus that depresses the sternum with a compressed-gas-powered plunger that has been affixed to a backboard. The patient’s thorax is positioned supine on the backboard, and the piston device is positioned above the patient with the plunger centered over the portion of the sternum where manual compressions should be applied. The device is then affixed to the backboard.

The device can be configured by the user to deliver a specific rate and depth of compressions. The benefits are that it allows for uniform delivery of compressions, with no diminishment in compression quality from rescuer fatigue, and it frees up an EMS provider to tend to other interventions. Limitations are that some piston devices, especially the first ones on the market, were large, heavy, and cumbersome. Also, since these devices operate on compressed gas, the device becomes useless when the compressed gas runs out. The available evidence can’t support routine use of these devices.

**Load-Distributing-Band CPR or Vest CPR**

This device is composed of a wide band that is applied to the chest circumferentially and, in some models, is attached to the backboard (Figure 15-17 ■). The device is either pneumatically or electrically driven to provide an inward constrictive pressure on the thorax, which, in turn, compresses the heart. Like the mechanical piston device, the obvious benefit is that it frees up one EMS provider to perform other care interventions. This device is also lighter than the mechanical piston device, is easy to apply, and has been shown to improve coronary and cerebral blood flow over traditional CPR. The available evidence can’t support routine use of these devices.

**Impedance Threshold Device**

An impedance threshold device (ITD) (Figure 15-18 ■) is actually a piece of equipment designed with a valve that limits the amount of air that enters the chest and lungs during the chest recoil phase of active compressions. The device is placed between the cuffed endotracheal tube of an intubated adult patient and the ventilatory adjunct being used to provide artificial ventilations.

Under normal conditions, the recoil of the chest during the relaxation phase of compressions creates a negative intrathoracic pressure. The pressure is then
normalized as air rushes into the lungs. With the impedance threshold device, however, air is prohibited from rushing in during the relaxation phase of ventilations, instead allowing the negative intrathoracic pressure to draw more blood toward the heart. This translates into a better cardiac filling for the next active compression. This device may be considered for use by the EMT in a nonintubated adult patient; however, it is absolutely necessary that a tight mask seal is constantly maintained.

Other Circulation-Enhancing Devices

Other circulation-enhancing devices have been developed from the concept of the impedance threshold device. These devices are used to actively compress and also decompress the thorax during resuscitation (Figure 15-19a and 15-19b). The compression phase generates the positive pressure to move the blood out of the heart through the arteries; decompression increases the negative pressure inside the thorax to improve blood return to the heart.
Using a Semiautomated AED

Ideally, at least two EMTs should be present—one to operate the AED, the other to perform CPR.

15-1A  In the unresponsive patient suspected of being in cardiac arrest, quickly assess for apnea or agonal ventilations and a pulse.

15-1B  One EMT should immediately initiate CPR beginning with chest compressions while the other EMT prepares the AED.

15-1C  Turn on the AED and follow the prompts.

15-1D  Apply the defibrillation pads while chest compressions are being performed. Minimize any interruption in chest compressions.

15-1E  Clear the patient for rhythm analysis.

15-1F  Deliver a defibrillation if advised.

continued
Shock is a critical condition that is related to a decrease in vascular volume, poor cardiac function, or vessel disturbances. Shock results in an inadequate delivery of oxygen and glucose to cells. This leads to a shift from aerobic to anaerobic cell metabolism. The lack of energy production and the buildup of acid begin to damage cells, tissues, and organs. If not managed effectively, multiple organ systems will fail and lead to death.

Shock is categorized as hypovolemic, distributive, cardiogenic, or obstructive. The names imply the actual etiology of the poor perfusion state. Types of shock include hemorrhagic hypovolemic, nonhemorrhagic hypovolemic, burn, anaphylactic, septic, neurogenic, and cardiogenic. Shock can progress through three stages: compensatory, decompensatory, and irreversible. Irreversible shock will eventually lead to death. The body responds to shock through direct sympathetic nervous system innervation of organs and structures and the release of various hormones. These are all designed to bring the body back to a normal state of perfusion and function. If the shock overwhelms these body responses or the hormones are exhausted, the shock progresses. The management of shock focuses on the airway, ventilation, oxygenation, circulation, and rapid transport.

To increase the survival rate from cardiac arrest, always remember the components of the Chain of Survival. Immediate recognition and activation, early CPR, rapid defibrillation, effective ACLS, and integrated post-cardiac-arrest care are all necessary if rates of patient survival from cardiac arrest are going to improve.

When caring for a patient in cardiac arrest, always do your best in each of the interventions you are providing. Remember to “push hard and push fast” with compressions so that the brain and heart can still receive blood flow during the arrest management. Minimize interruptions in chest compressions. Ensure adequate ventilations and provide oxygen during the arrest as well. The automated external defibrillator should be utilized specifically as addressed earlier in the chapter so that those patients in ventricular fibrillation will have the greatest opportunity for survival. Patients in nonventricular fibrillation cardiac arrest (identified by a “no shock” message on the AED) should also receive this high level of care so that they too may have the greatest chance for survival.

Finally, the patient near cardiac arrest, in cardiac arrest, or just coming out of cardiac arrest is probably one of the most challenging and dynamic situations the EMT will ever encounter. It requires a thorough understanding of the body, application of multiple skills simultaneously, and coordination of multiple EMS providers—all done in the shortest time possible so that the patient can be transported to the hospital for definitive care.
Scene Size-up
You have been dispatched for a 26-year-old male patient who has been stabbed in the leg and is bleeding profusely. You are directed into the house by a police officer. You find the patient lying supine on the floor with a large pool of blood around his right thigh.

Primary Assessment
As you approach the patient, he is not alert and doesn’t respond when you call his name. He also appears to be very pale. You instruct a police officer who is also an Emergency Medical Responder to take manual in-line spinal stabilization. The patient moans when you pinch and twist his trapezius muscle. You open the airway using a jaw thrust and inspect inside the oral cavity. The mouth is clear of any obstructions. You assess the rate and depth of breathing by listening for air movement and watching the chest rise. The respirations are rapid and the tidal volume is adequate. You instruct your partner to apply a nonrebreather mask at 15 lpm because shock and poor perfusion are suspected and to apply the pulse oximeter to attempt to get an SpO2 reading. The radial pulse is barely palpable and the skin is pale, cool, and clammy. Once the patient is completely immobilized, you quickly move him to the back of the ambulance and begin rapid transport to the level 1 trauma center.

There was no one at the scene from whom you could have gathered a history. You did not note any medical identification items on his body. The patient still remains only responsive to a painful stimulus; thus, he is not able to provide any history information.

Secondary Assessment
You recognize the signs the patient is exhibiting to be consistent with hypovolemic shock so you elect to do a rapid secondary assessment. You begin at the head and move systematically down to the toes inspecting and palpating for any other life-threatening injuries. You auscultate the breath sounds and find them to be equal and clear bilaterally. You log roll the patient to place him on a backboard. As you do so, you quickly cut away the clothing to the back and inspect and palpate for any other injuries. You place the patient on the backboard. While your partner finishes applying the immobilization equipment, you obtain a set of vital signs. His blood pressure is 72/58 mmHg, heart rate is 132 bpm, respirations are 26/minute with a good tidal volume, and his skin is pale, cool, and clammy. Once the patient is completely immobilized, you quickly move him to the back of the ambulance and begin rapid transport to the level 1 trauma center.

Reassessment
En route to the hospital you reassess the mental status, airway, ventilation, oxygenation, and circulation. You check the pressure dressing on the leg to be sure there is no additional bleeding. You obtain another set of vital signs. You contact the trauma center and provide a radio report of the assessment findings, your emergency care, and the ETA.

Upon arrival to the emergency department, the trauma surgeon meets you to bring the patient into the trauma bay. You provide an oral report and transfer the care of the patient. You then prepare your written report as your partner cleans and prepares the ambulance for another call.

Case Study Follow-up

IN REVIEW

1. Define shock.
2. Describe what is needed to maintain adequate cell perfusion.
3. List and describe the three etiologies of shock.
4. List and describe the categories of shock.
5. List and describe each type of shock.
6. List and describe the three stages of shock.
7. Describe the body’s neural and hormonal response to shock.
8. Explain the general principles of shock.
9. List the five links in the AHA chain of survival for the adult patient and for the pediatric patient.
10. Name and describe the heart rhythms that might benefit from defibrillation.
11. Describe patients for whom use of the AED is appropriate and those for whom it is not.
12. Explain how delivery of CPR is coordinated with use of the AED.
13. Name the procedures an EMT should follow in dealing with an adult patient with no pulse.
14. Explain the basic steps to follow if a resuscitated patient goes back into cardiac arrest during transport.
You and your partner, Claire Menzies, have responded to a report of a male in his 50s with breathing difficulty at 115 Clearwater Drive. En route, you receive an update that CPR is being performed at the scene. Dispatch also advises that the ALS team is being contacted and that fire and police vehicles have been sent in support.

Your ambulance and the fire and police vehicles arrive at the scene within moments of each other, 4 minutes after the call came in. There you observe a small crowd gathered around a male patient. A man and a woman are performing CPR. There do not appear to be any hazards associated with this scene, and only one patient is visible. Because the dispatcher advised of CPR in progress, you take the AED when leaving the ambulance. You and your partner have already donned gloves and eye protection while en route.

You find a man, possibly in his mid-50s, lying supine on the ground with effective bystander CPR in progress. The bystanders state that they began CPR immediately upon his collapse and called 911. The patient’s skin is slightly cyanotic. Claire begins to set up the semiautomated AED while chest compressions are continued. You apply the defibrillation pads to the chest, turn on the AED, and stop CPR. You direct one of two firefighters who have come to the scene to prepare to immediately resume chest compressions, while you instruct the other to prepare for ventilation with a bag-valve mask and high-concentration oxygen.

1. What assessment findings indicate that this patient is indeed in cardiac arrest?
2. Which components of the Chain of Survival have already been met?
3. Why is immediate defibrillation desirable?
4. What cardiac rhythm is this patient most likely going to show?
5. What is the compression/ventilation ratio going to be for this patient?
6. If the AED indicates that no shock is warranted, what should the next action of the care providers be?
Respiratory Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD • Medicine** (Content Area: Respiratory)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

16-1. Define key terms introduced in this chapter.
16-2. Explain the importance of being able to quickly recognize and treat patients with respiratory emergencies.
16-3. Describe the structure and function of the respiratory system, including:
   a. Upper airway
   b. Lower airway
   c. Gas exchange
   d. Inspiratory and expiratory centers in the medulla and pons
16-4. Demonstrate the assessment of breath sounds.
16-5. Describe the characteristics of abnormal breath sounds, including:
   a. Wheezing
   b. Rhonchi
   c. Crackles (rales)
16-6. Explain the relationship between dyspnea and hypoxia.
16-7. Differentiate respiratory distress, respiratory failure, and respiratory arrest.
16-8. Describe the pathophysiology by which each of the following conditions leads to inadequate oxygenation:
   a. Obstructive pulmonary diseases: emphysema, chronic bronchitis, and asthma
   b. Pneumonia
   c. Pulmonary embolism
   d. Pulmonary edema
   e. Spontaneous pneumothorax
   f. Hyperventilation syndrome
   g. Epiglottitis
   h. Pertussis
   i. Cystic fibrosis
   j. Poisonous exposures
   k. Viral respiratory infections
16-9. As allowed by your scope of practice, demonstrate administering or assisting a patient with self-administration of bronchodilators by metered-dose inhaler and/or small-volume nebulizer.
16-10. Differentiate between short-acting beta$_2$ agonists appropriate for prehospital use and respiratory medications that are not intended for emergency use.
16-11. Describe special considerations in the assessment and management of pediatric and geriatric patients with respiratory emergencies, including:
   a. Differences in anatomy and physiology
   b. Causes of respiratory emergencies
   c. Differences in management
16-12. Employ an assessment-based approach in order to recognize indications for the following interventions in patients with respiratory complaints/emergencies:
   a. Establishing an airway
   b. Administration of oxygen
   c. Positive pressure ventilation
   d. Administration/assistance with self-administration of an inhaled beta$_2$ agonist
   e. Expedited transport
   f. ALS backup
16-13. Given a list of patient medications, recognize medications that are associated with respiratory disease.
16-14. Use reassessment to identify responses to treatment and changes in the conditions of patients presenting with respiratory complaints and emergencies.
The respiratory system can be divided into three portions. The first two are the upper and lower airways, with the vocal cords (or glottic opening) being the transition between the two. The primary purpose of the upper and lower airways is the conduction of air into and out of the lungs. The third portion of the respiratory system consists of the lungs and accessory structures, which work in concert with the upper and lower airways to allow the oxygenation of body cells and the elimination of carbon dioxide from the bloodstream.

Case Study

As he leads you up narrow stairs to the third floor of the apartment complex, you scan the scene for safety hazards and note any obstacles that will make it difficult to extricate the patient from the building. Upon walking into the apartment, you note a young woman sitting upright on a kitchen chair, looking very scared, and leaning slightly forward with her arms locked in front of her to hold her up. Before you can even introduce yourself, she begins to speak one word at a time with a gasp for breath in between: “I—I—can’t—breathe.”

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from respiratory distress. Later, we will return to the case and apply the procedures learned.
Normal Breathing

Most patients you encounter as an EMT will be breathing normally. When referring to normal respiratory rates, you must remember that normal is defined differently for each individual patient group based on age and preexisting disease. For example, a 19-year-old sitting in a recliner breathing 24 times per minute is a fast rate and should raise a concern. However, a respiratory rate of 24 per minute in an elderly patient is considered to be near the average rate. The following findings are consistent with a patient who is breathing adequately:

- An intact (open) airway
- Normal respiratory rate
- Normal rise and fall of the chest
- Normal respiratory rhythm
- Breath sounds that are present bilaterally
- Chest expansion and relaxation that occurs normally
- Minimal-to-absent use of accessory muscles to aid in breathing

The following should also occur in a patient who is breathing adequately, provided that no other condition or injury is involved:

- Normal mental status
- Normal muscle tone
- Normal pulse oximeter reading (≥94%)
- Normal skin condition findings

Abnormal Breathing

Abnormal factors that are present in certain pulmonary (lung) conditions can decrease the efficiency of gas exchange across the alveolar-capillary membrane. They include:

- Increased width of the space between the alveoli and blood vessels
- Lack of perfusion of the pulmonary capillaries from the right ventricle of the heart
- Filling of the alveoli with fluid, blood, or pus

During periods of heightened respiratory effort, the body may employ accessory muscles to help change the size of the thorax (chest cavity) more aggressively in order to move air better. Clinically speaking, many of the findings consistent with respiratory distress come from the use of these accessory muscles during times of disease, stress, or injury.

Other accessory structures that are part of the respiratory system include the inspiratory and expiratory centers in the medulla and pons, located in the brainstem, which exert nervous control of breathing. These respiratory centers receive information about the oxygen and carbon dioxide content of the bloodstream from special sensors in the vascular system. Additionally, stretch receptors in the walls of the lungs provide information to the brainstem to prevent accidental overexpansion injuries, and irritant receptors in the walls of the bronchioles detect the presence of abnormalities such as excessive fluid, toxic fumes or smoke, or significant air temperature changes.

Finally, receptors near the alveoli, called juxta-capillary receptors, detect when the alveolar-capillary beds are becoming abnormally engorged with blood as a result of heart failure. These receptors are believed to play a role in the feeling of shortness of breath the patient may experience, and they may also promote shallow and rapid breathing.

Assessing Breath Sounds

During the physical exam, auscultation of breath sounds may provide additional evidence of breathing difficulty. The general complaint of breathing difficulty can result from a variety of conditions; therefore, being able to describe the type of breath sounds may be helpful to medical direction when you ask for a medication order.

To achieve the most accurate interpretation of breath sounds, it is important to auscultate in the appropriate fashion. Whenever feasible, have the patient sit upright and, while using the diaphragm end of your stethoscope over bare skin (never auscultate over clothing), instruct the patient to cough one or two times and then take deep rhythmic breaths (inhalation and exhalation) with his mouth open. You may need to instruct the patient a few times to make no airway/vocal sounds while he does this. Place the head of the stethoscope on the patient’s thorax, and listen the whole way through the phases of inhalation and exhalation. If necessary, listen to a few of the patient’s breaths (each breath including both inhalation and exhalation) at each auscultation location to ensure your interpretation of any abnormal breath sound. Finally, listen to sounds on one location of the body, and then listen to the exact location on the other side (mirror location), before moving on. The photos in EMT Skills 16-1 illustrate common locations for thoracic auscultation. Table 16-1 identifies the significance of these locations.

Three basic types of abnormal breath sounds that you might hear upon auscultation of the thorax may be early indicators of impending respiratory distress.

- Wheezing is a high-pitched, musical, whistling sound that is best heard initially on exhalation but may also be heard during inhalation in more severe cases. It is an indication of swelling and constriction of the inner lining of the bronchioles. Wheezing that is diffuse (heard over all the lung fields) is a primary indication for the administration of a beta, agonist medication by metered-dose inhaler or by small-volume nebulizer. Wheezing is usually heard in asthma, emphysema, and chronic bronchitis. It may also be heard in pneumonia, congestive heart failure, and other...
conditions when they cause bronchoconstriction. (These disorders will be discussed later in this chapter.) With severe obstruction of the lower airways by bronchoconstriction and inflammation, wheezing may be significantly diminished or absent, because the velocity of air movement through the bronchioles is no longer sufficient to produce the wheezing sound.

- **Rhonchi** are snoring or rattling noises heard upon auscultation. They indicate obstruction of the larger conducting airways of the respiratory tract by thick secretions of mucus. Rhonchi are often heard in chronic bronchitis, emphysema, aspiration, and pneumonia. One characteristic of rhonchi is that the quality of sound changes if the person coughs or sometimes even when the person changes position.

- **Crackles**, also known as **rales**, are bubbly or crackling sounds heard during inhalation. These sounds are associated with fluid that has surrounded or filled the alveoli or very small bronchioles. The crackling sound is commonly associated with the alveoli and terminal bronchioles “popping” open with each inhalation. The bases of the lungs posteriorly will reveal crackles first because of the natural tendency of fluid to be pulled downward by gravity. Crackles may indicate pulmonary edema or pneumonia. This type of breath sound typically does not change with coughing or movement.

### RESPIRATORY DISTRESS

The majority of patients you will encounter as an EMT will display an adequate respiratory effort (normal breathing). However, you may encounter a patient with inadequate breathing, or find that a patient who was initially breathing adequately has deteriorated to a point where breathing is inadequate and insufficient to sustain life.

Failing to breathe adequately, even for short periods of time, will result in **hypoxemia** (decreased oxygen in the bloodstream typically defined as an SpO2 reading of <94%) and cellular death, which will lead to all the other body systems starting to falter as well. For example, with failure of the respiratory system, the neurological system will fail and the patient's mental status will deteriorate. Failure of the respiratory system will also cause the cardiovascular system to fail, causing the patient to display vital sign changes and shock (hypoperfusion). One by one, the body’s systems will fail from failure of the respiratory system. If left untreated, a patient with inadequate breathing will die.

Respiratory emergencies may range from “shortness of breath,” or **dyspnea**, to complete respiratory arrest, or **apnea**, in which the patient is no longer breathing. These conditions can result from a large number of causes, but most typically they involve the respiratory tract or the lungs. Because quick intervention and appropriate emergency care could be life saving in a respiratory emergency, it is important for you to understand the anatomy and basic physiology of the respiratory tract and lungs and the techniques of airway management and artificial ventilation. For a review of these topics, see Chapter 7, “Anatomy, Physiology, and Medical Terminology,” and Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”

Shortness of breath, abnormal upper airway sounds, faster- or slower-than-normal breathing rates, poor chest rise and fall—these and other signs and symptoms of respiratory distress may be indications that the cells of the body are not getting an adequate supply of oxygen, a condition known as **hypoxia**.

These and other signs and symptoms may be directly caused by obstructions of airflow occurring in the upper or lower portions of the respiratory tract or from fluid or collapse in the alveoli of the lungs, causing poor gas exchange. If adequate breathing and gas exchange are not present, the lack of oxygen will cause the body...
cells to begin to die. Some cells become irritable when they are hypoxic, causing the cells to function abnormally. For example, hypoxic cardiac cells become irritable and begin to send out abnormal impulses, leading to cardiac dysrhythmias (abnormal heart rhythms).

Following is a listing of common findings the patient with respiratory distress may display:

- Subjective complaint of shortness of breath
- Restlessness
- Increased (early distress) or decreased (late distress) pulse rate
- Changes to the rate or depth of breathing
- Skin color changes
- Abnormal breathing, lung, or airway sounds
- Difficulty or inability to speak
- Muscle retractions (suprasternal, suprACLavicular, subCLavicular, intercostal)
- Altered mental status
- Abdominal breathing (excessive use of abdominal muscles)
- Excessive coughing (with or without expectorating material)
- Tripod positioning
- Decrease in pulse oximetry (blood oxygen saturation) reading, especially below 94%

Many complaints of breathing difficulty result from significant narrowing of the bronchioles of the lower airway from inflammation, swelling, or constriction of the muscle layer, a condition known as bronchoconstriction or bronchospasm. This narrowing causes a drastic increase in resistance to airflow in the bronchioles, making inhalation and particularly exhalation extremely difficult and producing wheezing. The patient may be prescribed a medication in aerosol form that can be inhaled during this episode of breathing difficulty. This medication, known as a bronchodilator, is designed to dilate (relax and open) the bronchioles, which results in an increase in the effectiveness of breathing and relief from the signs and symptoms.

Breathing difficulty may also be a symptom of injuries to the head, face, neck, spine, chest, or abdomen. A high index of suspicion and accurate assessment are required so no life-threatening injuries are missed. In addition, cardiac compromise, hyperventilation associated with emotional upset, and various abdominal conditions may produce difficulty in breathing.

Although several factors could lead to a patient complaining of dyspnea, the most common cause of this sensation of shortness of breath is dysfunction in the respiratory system. The sensation of shortness of breath occurs when the metabolic demands of the body are not being met. It is usually caused by one of the following:

1. Mechanical disruption to the airway, lung, or chest wall that prevents effective mechanical ventilation. Examples of conditions that may cause a disruption in mechanical ventilation include airway obstruction, flail chest (two or more adjacent ribs fractured in two or more places), chest muscle weakness, neuromuscular diseases, and lung collapse (pneumothorax).

2. Stimulation of the receptors in the lungs. Such stimulation will produce a sensation of shortness of breath. Conditions that will stimulate the receptors include asthma, pneumonia, and congestive heart failure.

3. Inadequate gas exchange at the level of the alveoli and capillaries causing a decrease in the oxygen content in the blood (hypoxemia) or a rise in the level of carbon dioxide. This may be due to:
   - a ventilation disturbance: an inadequate amount of oxygen-rich air entering the alveoli and passing across the alveolar membrane to the capillary;
   - a perfusion disturbance: an inadequate amount of blood traveling through the pulmonary capillaries, which decreases the number of red blood cells available to pick up the oxygen and transport it to the cells; or
   - both a ventilation and a perfusion disturbance in the lungs, leading to hypoxemia (decreased oxygen levels in the blood) and hypercarbia (increased carbon dioxide levels in the blood)

Regardless of the cause, a complaint of breathing difficulty requires your immediate intervention. If severe hypoxia is present, time is critical because of the detrimental effects of severely or prolonged low oxygen levels on all cells and organs.

A patient who is having difficulty breathing but has an adequate tidal volume and respiratory rate is said to be in respiratory distress. Because the tidal volume and respiratory rate are still adequate, the patient is compensating. Because there are signs of respiratory distress, however, supplemental oxygen should be administered. A nasal cannula at 2 to 4 lpm can be used to increase or maintain the SpO2 reading at 94% or higher. Oxygen administration should be based on the patient’s oxygenation status as measured and primarily guided by the pulse oximeter instead of using predetermined devices and flow rates for all patients. The patient who presents with moderate to severe respiratory distress and who is awake and alert may benefit from continuous positive pressure ventilation (CPAP). A patient presenting with a severely decreased SpO2 reading and obvious signs of severe hypoxia may benefit from higher concentrations of oxygen delivered by a nonrebreather mask at 15 lpm. The SpO2 of pregnant patients who present in respiratory distress should be maintained at a slightly higher level of ≥95% to maintain adequate oxygenation of the fetus.

If either the tidal volume or the respiratory rate becomes or is inadequate, the patient’s respiratory status becomes inadequate. The patient is said to be in respiratory failure, since the respiratory tidal volume or rate is no longer able to provide an adequate ventilatory effort. This requires you to immediately begin ventilation with a bag-valve-mask device or other ventilation device. Supplemental oxygen must be delivered through the ventilation device. If a patient with inadequate
breathing is not treated promptly, it is likely that he will deteriorate to respiratory arrest.

**Respiratory arrest** is when the breathing effort ceases completely. Respiratory arrest can lead to cardiac arrest in minutes, if not properly managed, because of a lack of oxygen delivery to the brain and heart. Whether breathing difficulty is caused by trauma or a medical condition, your first priority will be to determine if the patient is in respiratory distress and only in need of oxygen therapy, or if he is in respiratory failure or respiratory arrest where he will need immediate ventilation with a bag-valve mask or other ventilation device and supplemental oxygen.

**ASSESSMENT TIPS**

*Respiratory distress* patients will have an adequate chest rise (tidal volume) and an adequate respiratory rate. Since both the tidal volume and respiratory rate are adequate, the patient has adequate breathing and is only in need of supplemental oxygen. A patient in *respiratory failure* will have inadequate chest rise (tidal volume) or an inadequate respiratory rate or both. If either tidal volume or respiratory rate is inadequate, the respiratory status is inadequate and the patient needs immediate ventilation. Respiratory failure and respiratory arrest are treated the same way, with positive pressure ventilation and supplemental oxygen.

**PATHOPHYSIOLOGY OF CONDITIONS THAT CAUSE RESPIRATORY DISTRESS**

Many conditions may cause a patient to experience respiratory distress. Even though disease processes differ, the assessment and emergency care are basically the same. It is not your responsibility to diagnose the specific condition or disease causing the respiratory distress; however, you are responsible for identifying the signs and symptoms, determining whether the breathing is adequate or inadequate, anticipating deterioration in the patient’s status, and providing immediate intervention as necessary to support adequate respiration.

The following sections discuss the pathophysiology of a variety of diseases that may cause respiratory distress:

- Obstructive pulmonary diseases
  - Emphysema
  - Chronic bronchitis
  - Asthma
- Pneumonia
- Pulmonary embolism
- Pulmonary edema
- Spontaneous pneumothorax
- Hyperventilation syndrome
- Epiglottitis
- Pertussis
- Cystic fibrosis
- Poisonous exposures
- Viral respiratory infections

**Obstructive Pulmonary Diseases**

Responding to a call for a patient complaining of shortness of breath who has an obstructive pulmonary (lung) disease is common in the prehospital environment (Figure 16-1 ■). An obstructive lung disease causes an obstruction of airflow through the respiratory tract, leading to a reduction in gas exchange. The most severe consequence of reduced airflow is hypoxia.

The three most commonly encountered obstructive pulmonary diseases are emphysema, chronic bronchitis, and asthma. Emphysema and chronic bronchitis are chronic disease conditions that continue to progress. These patients are typically older and exhibit abnormal lung function and signs and symptoms of the disease continuously (chronically). Thus, emphysema and chronic bronchitis are referred to as chronic obstructive pulmonary disease (COPD) (Figure 16-2 ■). Many patients have a combination of chronic bronchitis and emphysema and present with a mixture of signs and symptoms associated with both conditions. In the past, the emphysema patient was referred to as the “pink puffer” and the chronic bronchitis patient

- FIGURE 16-1 Man suffering respiratory distress (indicated by tripod position) from obstructive lung disease.
was referred to as the “blue bloater.” We will explain later why these designations are no longer considered valid.

There is a direct causation between cigarette smoking and environmental toxins and the development of emphysema and chronic bronchitis. You may encounter a COPD patient who has a continuous positive airway pressure (CPAP) or a bilevel positive airway pressure (BiPAP) machine on the bedside stand, which the patient uses with a mask applied over the nose to assist in keeping airway passages open and providing adequate oxygenation while the patient is sleeping. Patients who suffer sleep apnea (periods of nonbreathing during sleep) may also use CPAP or BiPAP machines (Figure 16-3 ■). (For more extensive information on CPAP and BiPAP, review Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”)

Asthma patients are typically younger and, unlike emphysema and chronic bronchitis patients, have near normal or normal lung function between asthma attacks. Therefore, asthma is considered an obstructive pulmonary disease but is not categorized as a chronic obstructive disease (COPD). Asthma, which is thought to be passed on genetically, occurs in response to factors within the body (stress, exercise) and factors found in the environment (allergens, chemical fumes).

**Emphysema**

Emphysema is a permanent disease process distal to the terminal bronchiole that is characterized by destruction of the alveolar walls and distention of the alveolar sacs and a gradual destruction of the pulmonary capillary beds with a severe reduction in the alveolar/capillary area for gas exchange to occur. It is more common in men than in women. The primary cause of COPD is cigarette smoking. Persons who are exposed continuously to environmental toxins are also predisposed to developing emphysema.

**Pathophysiology.** In emphysema, the lung tissue loses its elasticity, the alveoli become distented with trapped air, and the walls of the alveoli are destroyed. Loss of the alveolar wall reduces the surface area in contact with pulmonary capillaries. Therefore, a drastic disruption in gas exchange occurs and the patient becomes progressively hypoxic and begins to retain carbon dioxide.

The distal airways also are involved and have a greatly increased airway resistance. Breathing is extremely difficult for the emphysema patient. Exhaling becomes an active rather than a passive process, requiring muscular contraction; therefore, the patient uses most of his energy to breathe. The patient will purse his lips while exhaling to create his own "physiologic PEEP." By doing so, he creates a backpressure in the distal bronchioles keeping them more open than if he didn’t purse his lips. This then requires less force and energy to move the air through the slightly more open distal bronchioles.

The patient usually complains of extreme shortness of breath upon exertion, which may be simply walking
across a room. The thin appearance from weight loss and muscle wasting is associated with a reduction in cardiac output and the high energy demands of the respiratory muscles required for breathing. The loss of lung elasticity and trapping of air cause the chest to increase in diameter, which produces the barrel-chest appearance typical with this disease.

The emphysema patient compensates for the disease process by hyperventilating. Because the patient hyperventilates, blood oxygen levels are maintained at a relatively normal level. This allows the patient to maintain a normal or “pink” appearance. The constant hyperventilation with pursed-lip breathing makes the patient appear as if he is puffing. Thus, the name “pink puffer” was given to the emphysema patient. However, as stated earlier, the COPD patient often has a combination of disease processes; thus, the designation of a patient with emphysema as a pink puffer is outdated.

Assessment. Many of the signs and symptoms of emphysema are similar to those listed earlier for respiratory distress and may include the following:

- Anxious, alert, and oriented
- Dyspneic
- Uses accessory muscles
- Thin, barrel-chest appearance from chronic air trapping in the alveoli causing the anterior–posterior diameter of the chest to increase
- Coughing, but with little sputum (material that is coughed up)
- Prolonged exhalation
- Diminished breath sounds
- Wheezing and rhonchi on auscultation
- Pursed-lip breathing (physiologic PEEP)
- Extreme difficulty of breathing on minimal exertion
- Pink complexion from chronic hyperventilation (emphysema patients were often called “pink puffers”; however, as already noted, this is outdated because many COPD patients don’t conform to the description)
- Tachypnea—breathing rate usually greater than 20 per minute at rest
- Tachycardia (increased heart rate)
- Diaphoresis (sweating; moist skin)
- SpO₂ reading may be 94% or greater unless in respiratory failure
- Tripod or hunched-over position
- May be on home oxygen

**Chronic Bronchitis**

Chronic bronchitis is a disease process that affects primarily the bronchi and bronchioles. Like emphysema, chronic bronchitis is associated with cigarette smoking. By definition, chronic bronchitis is characterized by a productive cough that persists for at least three consecutive months a year for at least two consecutive years.

Pathophysiology. Chronic bronchitis involves inflammation, swelling, and thickening of the lining of the bronchi and bronchioles and excessive mucus production. The alveoli remain unaffected by the disease; however, the inflamed and swollen bronchioles and thick mucus restrict airflow to the alveoli so that they do not expand fully, causing respiratory distress and possible hypoxia.

With the swelling and thickening of the lining of the lower airways and the increase in mucus production in chronic bronchitis, the airways become very narrow, causing a high resistance to air movement and chronic difficulty in breathing. Recurrent infections leave scar tissue that further narrows the airways. Unlike in emphysema, the pulmonary capillary bed is not damaged. The body responds to the bronchiole obstruction by reducing ventilation and increasing cardiac output. The severe mismatch between the reduced amount of ventilation available in the alveoli and the increased blood flow through the pulmonary capillary leads to hypoxemia, hypercapnia (retention of carbon dioxide in the blood), and the production of an increased number of red blood cells (polycythemia).

Because of the increase in bronchiole obstruction, there is a reduction in the residual volume in the lungs that leads to “bloating” and a “blue” (cyanotic) appearance. Thus, the patient with chronic bronchitis was once referred to as a “blue bloater.” Again, this reference is outdated because of the combination of disease processes found in COPD patients.

Assessment. The following are signs and symptoms of chronic bronchitis:

- Cough (hallmark sign) is prominent; vigorous coughing produces sputum
- Typically overweight, with prominent peripheral edema and chronic jugular vein distention
- Chronically cyanotic complexion (As already noted, chronic bronchitis patients were often called “blue bloaters,” but this is outdated because many COPD patients don’t conform to the description)
- Minimal difficulty in breathing and anxiety, unless in respiratory failure
- SpO₂ reading of <94%, indicating chronic hypoxemia
- Scattered rales and coarse rhonchi usually heard upon auscultation of the lungs
- Wheezes and, possibly, crackles at the bases of the lungs
- Asterixis (flapping of the extended wrists) may be seen in respiratory failure

This patient frequently suffers from respiratory infections that lead to more acute episodes.

**Emergency Medical Care for Emphysema and Chronic Bronchitis.** Emergency care for the patient with emphysema and chronic bronchitis follows the same guidelines as for any patient suffering from difficulty in breathing. Ensuring an open airway and
adequate breathing, position of comfort, and administration of supplemental oxygen if necessary are key elements in managing these patients. The patient may also have a prescribed metered-dose inhaler or small-volume nebulizer.

COPD patients may develop a hypoxic drive. Normally, the body’s respiratory receptors respond to rising carbon dioxide levels to stimulate breathing. In some COPD patients, constantly high carbon dioxide levels in the blood from poor gas exchange cause the respiratory receptors to become insensitive to CO2 and to respond, instead, to low levels of oxygen. Theoretically, if high concentrations of oxygen are administered to the patient, the receptors pick up the increased oxygen level in the blood and send signals to the respiratory control center to reduce or even stop breathing. This usually occurs when high concentrations of oxygen are administered over a long period of time, but can occur over a short period of time, especially in the chronic bronchitis patient.

In the prehospital setting, this is a rare event and is not a major concern. Oxygen administration should take precedence over a concern about whether the hypoxic drive is going to be lost and cause the patient to stop breathing. (If this should happen, you would initiate positive pressure ventilation with supplemental oxygen, as for any patient with inadequate ventilation.)

If you have categorized the COPD patient as being a high priority, if respiratory distress is evident, and if trauma, shock, cardiac compromise, or other potentially life-threatening conditions exist, oxygen should be administered to maintain the SpO2 at or above 94%, which may be achieved with a nasal cannula at 2–6 lpm. Since many COPD patients are on home oxygen, you may be advised to apply a nasal cannula at the same liter flow or possibly 1 lpm higher than the home oxygen setting. Follow local protocol or medical direction’s order for oxygen administration in the COPD patient. As a general rule, never withhold oxygen from any patient who requires it.

If your protocol allows, in severe cases of respiratory distress consider the use of continuous positive airway pressure (CPAP). (See Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”) CPAP in COPD is indicated if one or more of the following is present:

- Moderate to severe dyspnea with the use of accessory muscles and paradoxical abdominal movement
- Respiratory rate >25 per minute

A nasal or mask device can be used to deliver the CPAP. A pressure of 5 to 10 cmH2O is usually required (follow your local protocol). Continuously assess for signs of improvement (Table 16-2) or deterioration (Table 16-3) during the use of CPAP.

If the signs of deterioration continue to progress or are not improving immediately, remove the CPAP device and begin bag-valve-mask ventilation. Be sure to deliver supplemental oxygen to the BVM device.

### Table 16-2 Signs of Improvement During the Administration of CPAP

- Reduction in the complaint of dyspnea
- Improved SpO2 reading
- Stronger respiratory effort
- Patient becomes more alert

### Table 16-3 Signs of Deterioration During the Administration of CPAP

- Increasing respiratory rate
- Lethargy
- Patient is becoming more exhausted and fatigued
- Speechlessness
- Abdomen moves inward with inhalation and outward with exhalation
- Decreasing SpO2 reading

### Asthma

Asthma is a common respiratory condition that you may be called to the scene to manage. The most common complaint of the asthma patient is severe shortness of breath. Many asthma patients are aware of their condition and have medication to manage the disease and its signs and symptoms. You may be called to the scene for a patient who is suffering an early-onset asthma attack or one in which the patient’s medication is not reversing the attack.

**Pathophysiology.** Asthma is characterized by an increased sensitivity of the lower airways to irritants and allergens, causing bronchospasm, which is a diffuse, reversible narrowing of the bronchioles, as well as inflammation to the lining of the bronchioles. The following conditions in the asthma patient contribute to the increasing resistance to airflow and difficulty in breathing (Figure 16-4):

- Bronchospasm (constriction of the smooth muscle in the bronchioles)
- Edema (swelling) of the inner lining in the airways
- Increased secretion of mucus that causes plugging of the smaller airways

Asthma patients usually suffer acute, irregular, periodic attacks, but between the attacks they usually have either no or very few signs or symptoms. A prolonged life-threatening attack that produces inadequate breathing and severe signs and symptoms is called *status asthmaticus*. Status asthmaticus is a severe asthmatic attack that does not respond to either oxygen or medication. Patients in status asthmaticus require immediate and rapid transport to the hospital. Consider requesting ALS backup.

There are generally two kinds of asthma. Extrinsic asthma, or “allergic” asthma, usually results from a
Diaphoresis secondary due to an increase in the work of breathing, if profound it is usually accompanied by a decreasing level of agitation and altered mental status.

- Anxiety and apprehension
- Speaks in sentences (mild), phrases (moderate), or only words or syllables (severe)
- Possible fever (may be triggered by an upper respiratory tract infection)
- Typical allergic signs and symptoms: sneezing, red or bloodshot eyes, stuffy nose
- Runny nose (rhinitis) is found in approximately 80% of cases
- Chest tightness
- Inability to sleep; dyspnea often worsens at night
- $\text{SpO}_2 < 94\%$
- Symptoms of gastroesophageal reflux
- Pulsus paradoxus (drop in systolic blood pressure of $>10$ mmHg during inhalation) indicates a severe asthma attack
- Reduction in the peak expiratory flow rate (PEFR), which is often measured regularly by asthmatics on maintenance therapies

Approximately 80 percent of the cases of asthma have a slow onset (referred to as slow-onset asthma) with deterioration over a minimum of 6 hours to several days. This type is more prevalent in females and is usually triggered by an upper respiratory tract infection. These patients typically have a greater degree of bronchiole inflammation and a slower response to treatment.

Sudden-onset asthma occurs in approximately 20 percent of cases and presents with rapid deterioration within the first 6 hours after onset. This type occurs more often in males and is usually triggered by allergens, exercise, or stress. This type of asthma is associated with greater bronchiole smooth muscle constriction and a better and faster response to treatment.

Indicators of a critically ill asthma attack patient are as follows:

- Upright position
- Signs and symptoms of severe respiratory distress
- Tachypnea ($>20$/minute and often $>40$/minute)
- Tachycardia (usually $>120$ bpm)
- Pulsus paradoxus
- Diaphoresis
- Accessory muscle use
- Speech is single words or syllables
- Wheezing may be absent due to severe bronchiole obstruction and minimal airflow
- Decreasing consciousness and bradypnea indicate severe hypercarbia and the progression from respiratory distress to impending respiratory failure
- Extreme fatigue or exhaustion; the patient is too tired to breathe
- $\text{SpO}_2 < 90\%$ with supplemental oxygen
The asthma patient presenting with signs and symptoms of being critically ill will require positive pressure ventilation and supplemental oxygen. If the patient is awake, alert, and able to obey commands, CPAP may be used. Watch for signs of deterioration and the need to begin bag-valve-mask ventilation.

**Emergency Medical Care.** During the primary assessment, you would have established and maintained an airway, applied oxygen or begun positive pressure ventilation with supplemental oxygen, and assessed the adequacy of circulation. Because the complaint of dyspnea is characteristic of an asthma attack, all patients having an asthma attack should receive supplemental oxygen to maintain an SpO₂ of 94% or greater. If signs of severe hypoxia are not present, this usually can be achieved by using a nasal cannula. In the pregnant patient and those with preexisting cardiac disease, maintain an SpO₂ of ≥95%. Humidification of the oxygen is not necessary; however, it might be helpful in rehydrating the airways. When providing positive pressure ventilation to a patient suffering a severe asthma attack in respiratory failure or arrest, the increase in resistance in the bronchioles will make ventilation more difficult to perform. The person operating the bag-valve mask will feel significant resistance when squeezing the bag. Watch for chest rise when providing ventilation to determine the necessary volume and pressure needed to effectively ventilate the patient. You must allow sufficient time for exhalation. Aggressive positive pressure ventilation may increase the amount of air trapped in the alveoli, increasing the pressure inside the chest and causing lung injury. High pressure will also result in reduced cardiac output. Deliver the ventilation with a bag-valve-mask device at a maximum rate of 10 to 12 times per minute.

CPAP may be beneficial in the acute asthma patient in respiratory distress or very early respiratory failure who is awake, alert, oriented, and able to obey commands (GCS >10), is breathing on his own, is able to maintain his own airway, and has an SpO₂ reading of <94%. CPAP administered to the asthma patient will improve oxygenation and decrease respiratory muscle fatigue by increasing the residual volume of air in the lungs, improving lung compliance, and reducing the work required to inflate the lungs during inhalation. (See Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”)

During the physical exam, it is necessary to calm the patient to reduce his workload of breathing and oxygen consumption. If the patient has a prescribed metered-dose inhaler or small-volume nebulizer, administration of the beta agonist medication should provide some relief of the breathing difficulty. Administration of the beta₂ agonist and CPAP could be done concurrently and with the proper equipment. Transport the patient, and continuously reassess the breathing status.

**Other Conditions That Cause Respiratory Distress**

**Pneumonia**

Pneumonia is a common cause of death in the United States, especially in the elderly. Patients infected with the human immunodeficiency virus (HIV) and others who are on immunosuppressive drugs, such as transplant patients, are also very prone to pneumonia. Additional risk factors include cigarette smoking, alcoholism, and exposure to cold temperatures.

**Pathophysiology.** Pneumonia is primarily an acute infectious disease caused by bacterium or a virus that affects the lower respiratory tract and causes lung inflammation and fluid- or pus-filled alveoli (Figure 16-5). This leads to a ventilation disturbance in the alveoli with poor gas exchange, hypoxemia, and eventual cellular hypoxia. Pneumonia can also be caused by inhalation of toxic irritants or aspiration of vomitus and other substances.

**Assessment.** The signs and symptoms of pneumonia vary with the cause and the patient’s age. The patient generally appears ill and may complain of fever and severe chills. Look for the following signs and symptoms:

- Malaise and decreased appetite
- Fever (may not occur in the elderly)
- Cough—may be productive or nonproductive
- Dyspnea (less frequent in the elderly)
- Tachypnea and tachycardia
- Chest pain—sharp and localized and usually made worse when breathing deeply or coughing
- Decreased chest wall movement and shallow respirations
- Splinting of thorax by patient with his arm
- Crackles, localized wheezing, and rhonchi heard on auscultation
- Altered mental status, especially in the elderly
- Diaphoresis
- Cyanosis
- SpO₂ <94%

**Emergency Medical Care.** The pneumonia patient is managed no differently from any patient having difficulty in breathing. Ensure the patient has an adequate...
airway, ventilation, and oxygenation. Administer supplemental oxygen via a nasal cannula at 2 to 4 lpm to maintain an SpO₂ of ≥94%. In severe cases of hypoxia, a nonrebreather may be used. This is an acute infectious disease process that is not usually associated with severe bronchoconstriction, unless it occurs as a complication of asthma or COPD. Therefore, you would not expect the patient to have a metered-dose inhaler or small-volume nebulizer for this condition, nor would you necessarily consider their use unless indications of bronchoconstriction are present. Consult medical direction and follow your local protocol for the use of the metered-dose inhaler or small-volume nebulizer and the administration of CPAP.

**Pulmonary Embolism**

In pulmonary embolism, an obstruction of blood flow in the pulmonary arteries leads to hypoxia. Patients at risk for suffering a pulmonary embolism are those who experience long periods of immobility (such as bedridden individuals, those who travel for a long period confined in one position, those with splints to extremities) as well as those with heart disease, recent surgery, long-bone fractures, venous pooling associated with pregnancy, cancer, deep vein thrombosis (development of clots in the veins, most commonly in the legs), estrogen therapy, clotting disorders, history of previous pulmonary embolism, and those who smoke.

**Pathophysiology.** Pulmonary embolism is a sudden blockage of blood flow through a pulmonary artery or one of its branches. The embolism is usually caused by a blood clot, but it may also be caused by an air bubble, a fat particle, a foreign body, or amniotic fluid (Figure 16-6). The embolism prevents blood from flowing to the lung. As a result, some areas of the lung have oxygen in the alveoli (adequate ventilation) but are not receiving any blood flow (reduced perfusion). Based on the ventilation/perfusion ratio, pulmonary embolism creates cellular hypoxia through a disturbance on the perfusion side by blocking blood flow to ventilated and oxygenated alveoli. The degree of the perfusion disturbance and the resulting cellular hypoxia is governed by the size of the embolus and the vessel that is blocked. A larger embolus blocks a larger vessel and reduces perfusion to a larger number of pulmonary capillaries, causing a greater severity of hypoxia.

**Assessment.** Signs and symptoms of pulmonary embolism depend on the size of the obstruction. If a clot obstructs a large artery, gas exchange will be severely impaired and signs and symptoms of respiratory distress will be evident. Suspect pulmonary embolism in any person with a sudden onset of unexplained dyspnea and chest pain (typically sharp and localized to a specific area of the chest) and signs of hypoxia, but who has normal breath sounds and adequate volume. The following are signs and symptoms of pulmonary embolism. However, it is important to note that the signs and symptoms of pulmonary embolism are often nonspecific and nondiagnostic.

- Sudden onset of unexplained dyspnea
- Signs of difficulty in breathing or respiratory distress; rapid breathing
- Sudden onset of sharp, stabbing chest pain
- Cough (may cough up blood)
- Tachypnea
- Tachycardia
- Syncope (fainting)
- Cool, moist skin
- Restlessness, anxiety, or sense of doom
- Decrease in blood pressure or hypotension (late sign)
- Cyanosis (may be severe) (late sign)
- Distended neck veins (late sign)
- Crackles
- Fever
- SpO₂ <94%
- Signs of complete circulatory collapse

It is important to note that not all of the signs and symptoms will always be present with pulmonary embolism. The three most common are chest pain, dyspnea, and tachypnea (rapid breathing).

**ASSESSMENT TIPS**

In any patient complaining of shortness of breath, assess for pain, redness, increased warmth, and swelling to the lower leg, especially at the calf. These are signs of a deep vein thrombosis (DVT), a blood clot in a vein of the lower leg that may have broken free, traveled to the lungs, and caused a pulmonary embolism.

**Emergency Medical Care.** During the primary assessment, you would have opened the airway and would have initiated positive pressure ventilation with supplemental oxygen or applied supplemental oxygen.
to maintain an \( \text{SpO}_2 \) reading of \( \geq 94\% \). It is important to begin oxygen administration early on and to continuously monitor the patient for signs of respiratory arrest. Immediately transport the patient.

**Acute Pulmonary Edema**

Pulmonary edema is most frequently seen in patients with cardiac dysfunction leading to congestive heart failure. Other disease processes could also lead to pulmonary edema. The most significant problem associated with pulmonary edema is hypoxia.

**Pathophysiology.** Acute pulmonary edema occurs when an excessive amount of fluid collects in the spaces between the alveoli and the capillaries (Figure 16-7 ■).

This intrusion of fluid disturbs normal gas exchange by reducing the ability of oxygen and carbon dioxide to diffuse across the alveolar-capillary surface because of the collection of water in the alveoli and between the alveoli and capillaries (ventilation side of the ventilation/perfusion ratio), which makes less oxygen available to the blood flowing through the capillaries (perfusion). This leads to hypoxemia and cellular hypoxia. In order to increase oxygenation of the blood passing through the pulmonary capillaries, the ventilation side of the ventilation/perfusion ratio must be improved. This can be done through CPAP or positive pressure ventilation and the use of supplemental oxygen. CPAP and positive pressure ventilation work by increased pressure on the alveolar side, pushing water back into the pulmonary capillaries.

There are two kinds of pulmonary edema: cardiogenic and noncardiogenic. Cardiogenic pulmonary edema is typically related to an inadequate pumping function of the heart that drastically increases the pressure in the pulmonary capillaries, which in turn forces fluid to leak into the space between the alveoli and capillaries and, eventually, into the alveoli themselves.

Noncardiogenic pulmonary edema, also known as acute respiratory distress syndrome (ARDS), results from destruction of the capillary bed that allows fluid to leak out. Common causes of noncardiogenic pulmonary edema are severe pneumonia, aspiration of vomitus, submersion, narcotic overdose, inhalation of smoke or other toxic gases, ascent to a high altitude, sepsis, and trauma. The causes may differ, but the signs and symptoms are the same.

**Assessment.** The following are signs and symptoms of pulmonary edema:

- Dyspnea, especially on exertion
- Difficulty in breathing when lying flat (orthopnea)
- Frothy sputum
- Tachycardia
- Anxiety, apprehension, combativeness, confusion
- Tripod position with legs dangling
- Fatigue
- Crackles and possibly wheezing on auscultation
- Cyanosis or dusky-color skin
- Pale, moist skin
- Distended neck veins (cardiogenic cause only)
- Swollen lower extremities (cardiogenic cause only)
- Cough
- Symptoms of cardiac compromise (cardiogenic cause only)
- \( \text{SpO}_2 \leq 94\% \)

**FIGURE 16-7** Fluid that collects between the alveoli and capillaries, preventing normal exchange of oxygen and carbon dioxide. The fluid may also invade the alveolar sacs.
Emergency Medical Care. It is necessary to carefully assess the patient with pulmonary edema. If there is any evidence of inadequate breathing, you need to begin positive pressure ventilation with supplemental oxygen. CPAP may be extremely beneficial in the acute pulmonary edema patient in respiratory distress or very early respiratory failure who is awake, alert, oriented, and able to obey commands (GCS >10), is breathing on his own, is able to maintain his own airway, and has an SpO2 reading of <94%. The positive pressure will force the oxygen across the alveoli and into the capillaries and improve lung compliance, which will increase oxygenation of the blood and reduce cellular hypoxia. Always explain the procedure to the patient, who is already anxious and likely agitated. (See Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”)

If the patient doesn’t fit the criteria for CPAP, deteriorates to respiratory failure or arrest, is not responding to CPAP administration, or has inadequate ventilation, you must perform bag-valve-mask ventilation with supplemental oxygen.

If the breathing is adequate but respiratory distress is evident, administer oxygen via nonrebreather mask at 15 lpm and closely monitor the breathing status. Keep the patient in an upright sitting position and transport without delay.

Spontaneous Pneumothorax

A spontaneous pneumothorax is a sudden rupture of a portion of the visceral lining of the lung, not caused by trauma, that causes the lung to partially collapse. Males are five times more likely to suffer a spontaneous pneumothorax than females. Most of these males are tall, thin, lanky, and between the ages of 20 and 40. Many also have a history of cigarette smoking or a connective tissue disorder such as Marfan syndrome or Ehlers-Danlos syndrome. Patients with a history of COPD are more prone to spontaneous pneumothorax as a result of areas of weakened lung tissue called blebs.

Pathophysiology. In spontaneous pneumothorax, a portion of the visceral pleura ruptures without any trauma having been applied to the chest. This allows air to enter the pleural cavity, disrupting its normally negative pressure and causing the lung to collapse. The lung collapse causes a disturbance in gas exchange and can lead to hypoxia. It is thought that the reason tall, thin, lanky males are more likely to suffer a spontaneous pneumothorax is that the visceral pleura is stretched within the chest cavity beyond its normal limit. Often the stretched and weakened area ruptures when the patient experiences an increase in intrathoracic pressure from an activity such as coughing, lifting a heavy object, or straining (Figure 16-8 ■).

Assessment. A key finding in spontaneous pneumothorax is a sudden onset of shortness of breath without any evidence of trauma to the chest and with decreased breath sounds upon assessment. The signs and symptoms of a spontaneous pneumothorax are as follows:

- Sudden onset of shortness of breath
- Sudden onset of sharp chest pain or shoulder pain
- Decreased breath sounds to one side of the chest (most often heard first at the apex, or top, of lung)
- Subcutaneous emphysema (may be found)
- Tachypnea
- Diaphoresis
- Pallor
- Cyanosis (may be seen late and in a large or tension pneumothorax)
- SpO2 <94%

Assessment Tips

If a patient presents with a sudden onset of shortness of breath with decreased breath sounds to one side of the chest and no evidence of trauma, you should suspect a possible spontaneous pneumothorax.
Emergency Medical Care. The patient with a spontaneous pneumothorax may require supplemental oxygen to maintain an SpO₂ of ≥94% if the patient presents with signs of respiratory distress, chest pain, or any other indicators for oxygen administration. If inadequate breathing is present, it is necessary to provide positive pressure ventilation. Positive pressure ventilation in a patient suffering from a pneumothorax must be performed with great care, since the pneumothorax could easily be converted into a tension pneumothorax (air entering the pleural cavity that cannot escape, eventually causing lung collapse). Use the most minimal tidal volume necessary to ventilate the patient effectively. If cyanosis, hypotension, and significant resistance to ventilation occur, suspect a tension pneumothorax. The pulse oximeter reading will also decline severely with the development of a tension pneumothorax. Contact ALS backup if you suspect a tension pneumothorax.

CPAP is contraindicated in a patient with a suspected pneumothorax regardless of the complaint of dyspnea and evidence of respiratory distress. The positive pressure may increase the size of the pneumothorax and worsen the hypoxia.

**Hyperventilation Syndrome**

Hyperventilation syndrome is frequently encountered in the prehospital setting. It is commonly associated with situations in which the patient is emotionally upset or very excited. Patients suffering “panic attacks” will also suffer from hyperventilation syndrome. Although hyperventilation syndrome is most often associated with an anxious patient, it is important to recognize that hyperventilation syndrome can be caused by a serious medical problem. Therefore, always consider an underlying medical cause of hyperventilation syndrome when assessing and providing emergency medical care.

**Pathophysiology.** The hyperventilation syndrome patient is often anxious and experiences the feeling of not being able to catch his breath. The patient then begins to breathe faster and deeper, causing many of the signs and symptoms of hyperventilation to occur. The true hyperventilation syndrome patient begins to “blow off” excessive amounts of carbon dioxide. A certain level of carbon dioxide is necessary for the body to function normally. When too much carbon dioxide has been eliminated through rapid breathing, the patient begins to experience worsened signs and symptoms of hyperventilation syndrome. The patient becomes more anxious because of the symptoms, and breathes even faster. One result is that the amount of calcium in the body decreases, causing the muscles of the feet and hands to cramp.

**Assessment.** Most often, the patient with true hyperventilation syndrome will be found in an emotionally charged situation that is producing an anxious state in the patient. The following are signs and symptoms of hyperventilation syndrome:

- Fatigue
- Nervousness and anxiety
- Dizziness
- Shortness of breath
- Chest tightness
- Numbness and tingling around the mouth, hands, and feet
- Tachypnea
- Tachycardia
- Spasms of the fingers and feet causing them to cramp (carpopedal spasm)
- May precipitate seizures in a patient with a seizure disorder

**PATHOPHYSIOLOGY PEARLS**

The light-headedness, dizziness, or fainting experienced by the hyperventilating patient is caused by a drastic reduction of carbon dioxide (the rapid breathing blows off excessive amounts of carbon dioxide). This causes the cerebral arteries to constrict excessively, reducing blood flow to the brain tissue, causing the light-headedness, dizziness, and fainting.

Emergency Medical Care. The primary management is to get the patient to calm down and slow his breathing. Remove the patient from the source of anxiety or remove the source of anxiety from the scene, if possible. For example, if the scene involves a domestic dispute, removing the other person involved in the dispute may calm the patient. Instruct the patient to consciously slow down his rate of breathing and the amount of air he is breathing. One technique is to have the patient close his mouth and breathe through his nose. You may need to coach the patient to help him slow his rate of breathing. Do not have the patient breathe into a paper bag or oxygen mask not connected to oxygen to allow him to rebreathe carbon dioxide. These techniques can be fatal if the patient has a true underlying medical condition that is causing the hyperventilation syndrome. Only use a carbon dioxide rebreathing technique if no underlying medical conditions exist and you are specifically instructed by medical direction to do so. Keep in mind that conditions such as pulmonary embolism and myocardial infarction can present very similarly to hyperventilation syndrome. These are two of the conditions in which rebreathing carbon dioxide could be fatal.

If the patient has an SpO₂ reading of <94% or any other signs of hypoxia or hypoxemia, administer supplemental oxygen. This can be initiated with a nasal cannula at 2 lpm and titrated upward to achieve an SpO₂ reading of 94% or greater.
**Epiglottitis**

Epiglottitis, an inflammation affecting the upper airway, can be an acute, severe, life-threatening condition if left untreated. There is no age or season of prevalence associated with adult epiglottitis; however, males and smokers are more commonly affected. Although its incidence is low in the pediatric population, the incidence of adult epiglottitis has increased. The most common cause for epiglottitis in the adult population is *Haemophilus influenzae* type B. Due to the H. influenza vaccination, the incidence of epiglottitis in the pediatric patient population has significantly decreased. Adult epiglottitis can also occur as a result of a thermal injury.

**Pathophysiology.** As you recall, the epiglottis is a triangular cartilaginous structure that attaches at its base and closes over the glottic opening (opening to the larynx) during swallowing to prevent food or liquid from getting into the trachea. In epiglottitis, the epiglottis, area around the epiglottis, and base of the tongue become infected. As the condition progresses, the epiglottis and base of the tongue become inflamed and swollen, leading to a compromised airway and resultant respiratory compromise (Figure 16-9 ■). If untreated, this partial-to-complete airway obstruction leads to ineffective gas exchange in the lungs, hypoxia, acidosis, and eventually death.

**Assessment.** The following are signs and symptoms of epiglottitis:

- Upper respiratory tract infection, usually for 1 to 2 days prior to onset
- Dyspnea, usually with a more rapid onset
- High fever (although it can occur with only mild fevers)
- Sore throat and pharyngeal pain
- Inability to swallow with drooling (late sign of impending failure)
- Anxiety and apprehension
- Tripod position, usually with jaw jutted forward (late sign of impending failure)
- Fatigue
- High-pitched inspiratory stridor
- Cyanosis
- Trouble or pain during speaking
- SpO₂ <94%

**ASSESSMENT TIPS**

Inspiratory stridor is an indication of an almost completely occluded airway. It is created when the patient breathes in sharply in order to draw air past the airway obstruction. As air passes through the narrowed glottic opening, airflow becomes turbulent and it creates the high-pitched sound. If the inspiratory stridor disappears and your patient’s mental status continues to deteriorate, it probably means that total airway occlusion has occurred. ■

**Emergency Medical Care.** Treatment of epiglottitis is focused on ensuring oxygenation and preventing airway obstruction. If the patient’s breathing is still adequate, the first step is administration of high-concentration oxygen at 15 lpm to maximize oxygenation of the alveoli receiving airflow. In addition, and especially for the younger patient, maintaining a calm and quiet environment will help the patient to remain calm, and lessen the burden of respiratory distress. Keep the patient in a position that is comfortable to him, and expedite transport with ALS intercept if possible.

There is absolutely no need to force an inspection of the airway so long as the patient is adequately exchanging air, and it should not be attempted. Any additional irritation to the inflamed epiglottis may result in additional swelling that totally occludes the airway. In fact, attempting airway maneuvers in a patient with epiglottitis is only warranted in those extreme cases of respiratory occlusion from the swollen airway structures.

If the patient continues to deteriorate and requires assisted ventilations with a bag-valve-mask device, squeeze the bag slowly. This will help direct the air past the obstruction and into the lungs rather than into the esophagus to inflate the stomach. If this is not effective in ventilating the patient, it is a situation of complete airway obstruction at the level of the epiglottis, and an ALS provider may need to consider other advanced airway techniques.

**Pertussis**

Pertussis (also known as “whooping cough”) is a respiratory disease that is characterized by uncontrolled coughing. It is a highly contagious disease that affects the respiratory system and is caused by bacteria that reside in the upper airway of an infected person. It is spread by respiratory droplets that are discharged from the nose and mouth during coughing. Pertussis has been found to occur in all age brackets, but it is most reported...
in children. Generally speaking, the younger the patient, the more severe the clinical condition that develops.

**Pathophysiology.** Pertussis typically starts out seeming very similar to a cold or a mild upper respiratory infection. Because of this, an older patient or the parents of an infant or child may try “waiting it out” before seeking medical care. Thus by the time the patient presents to EMS, the condition may be severe. Within 2 weeks or so of onset, the patient will develop episodes of rapid coughing (15 to 24 episodes in close sequence) as the body attempts to expel thick mucus from the airway, followed by a “crowing” or “whooping” sound made during inhalation as the patient breathes in deeply.

Complications of pertussis include pneumonia, dehydration, seizures, brain injuries, ear infections, and even death. Most deaths occur to younger patients who have not been immunized for this disease, or to those patients who are exposed before finishing the vaccination series. In younger patients, the ongoing and uncontrolled coughing can severely disrupt normal breathing, diminish gas exchange in the alveoli, and promote bacterial pneumonia.

**Assessment.** Signs and symptoms of pertussis are as follows:

- History of upper respiratory infection
- Sneezing, runny nose, low-grade fever
- General malaise (weakness, fatigue, not feeling well)
- Increase in frequency and severity of coughing
- Coughing fits, usually more common at night
- Vomiting
- Inspiratory “whoop” heard at the end of coughing burst
- Possible development of cyanosis during coughing burst
- Diminishing pulse oximetry finding
- Exhaustion from expending energy during coughing burst
- Trouble speaking and breathing (dyspnea) during burst

**ASSESSMENT TIPS**

Pertussis actually has three stages. Stage 1 is characterized by findings consistent with a common cold or upper respiratory infection. In stage 2, coughing continues to worsen to the point that medical care is sought (EMS is summoned), and thus the suspicion for pertussis (whooping cough) is formed. Stage 3 is the recovery stage, and recovery is usually gradual, taking several weeks until a resolution is reached.

**Emergency Medical Care.** Treatment of pertussis is similar to the treatment for many other respiratory problems. It is focused on ensuring oxygenation, reversing hypoxemia, and preventing airway obstruction. The patient should remain in a comfortable position, and the EMT should administer supplemental oxygen to maintain an SpO₂ of ≥94%. The EMT should also encourage the patient to expectorate any mucus that is brought up with the coughing. The administration of humidified oxygen may help the mucus become less viscous and be expelled more easily. In addition, the patient will probably be anxious and/or scared, so the EMT should also try to ensure a quiet and calm environment. Expedite transport and consider an ALS intercept.

Finally, remember that this is a very contagious disease, and the EMT should take all precautions necessary to prevent cross-contamination (to include putting a surgical mask on the patient to catch expelled airway droplets), so long as it does not impede the patient's breathing. Following transport of a patient with known or suspected pertussis, consider totally disinfecting the patient compartment of the ambulance.

**Cystic Fibrosis**

Cystic fibrosis (also known as CF, mucoviscidosis, or mucoviscoidosis) is a hereditary disease. Although it commonly causes pulmonary dysfunction as a result of changes in the mucus-secreting glands of the lungs, it also affects the sweat glands, the pancreas, the liver, and the intestines.

The pulmonary complications are the most common cause for a patient with this affliction to summon EMS. There is not yet a cure for CF, and many individuals with this disease die at a young age (20s to 30s) as a result of pulmonary failure. In fact, CF is cited as one of the most common life-shortening genetic diseases. Because it is possible to detect CF in a patient at a very young age, it is common for the patient experiencing a crisis to already know of this diagnosis. Fortunately, medical research and treatment is lengthening the life span of some people to as high as 50 years. In terminal stages of the disease, the final medical recourse is lung transplantation when all other interventions have failed.

**Pathophysiology.** Lining most all of the respiratory tree in the body is a layer of tissue that is coated with a mucous lining. This mucus lining is normally watery and helps to warm and humidify inspired air. It also serves to trap any inhaled particles. In cystic fibrosis, however, an abnormal gene alters the functioning of the mucus glands lining the respiratory system and there is an overabundant production of mucus, which is very thick and sticky. As this thick mucus layer develops, there is blockage of the airways as well as an increase in the incidence of lung infections, since bacteria can readily grow in the thick mucus. Repeated lung infections in turn cause scarring of the lung tissue and promote ongoing pulmonary damage. As a result, there is progressive diminishment in the efficiency of respiratory function, which leads to eventual pulmonary failure and death.

**Assessment.** The following are signs and symptoms of cystic fibrosis:

- Commonly a known history of the disease
- Recurrent coughing
- General malaise (weakness, fatigue, not feeling well)
- Expectoration of thick mucus during coughing
• Recurrent episodes or history of pneumonia, bronchitis, and sinusitis
• Gastrointestinal complaints that may include diarrhea and greasy and/or foul-smelling bowel movements
• Abdominal pain from intestinal gas
• Malnutrition or low weight despite a healthy appetite
• Dehydration
• Clubbing of the digits
• Trouble speaking and breathing (dyspnea) with mucus buildup
• Signs of pneumonia

**ASSESSMENT TIPS**

Although the most common complaint patients with CF will have when they present to EMS is difficulty in breathing, many of the other findings are due to dysfunction of other organ systems. The abdominal findings such as dehydration, bowel changes, and poor weight gain are from the damage the disease inflicts on the gastrointestinal tract. Pancreatitis can also cause abdominal pain as does liver damage from the disease.

**Emergency Medical Care.** Emergency treatment of a patient suffering from exacerbation of CF is geared toward symptomatic relief of the respiratory distress. If the patient is breathing adequately, he should be provided with supplemental oxygen to maintain an SpO2 of 94% or greater. If the patient is expectorating thick mucus, humidification of the oxygen will help thin the secretions so that expelling them with coughing will become easier. The EMT may also consider administering normal saline through a small-volume nebulizer to aid in this. (Follow local protocol or medical direction.) The patient should remain in a sitting position for comfort and to aid in breathing. Establish ongoing pulse oximetry and, in severe cases, attempt to rendezvous with an ALS unit. If the patient's condition is severe enough that breathing becomes inadequate, the EMT will have to deliver oxygen via positive pressure ventilation.

**Poisonous Exposures**

Thousands of people die each year from exposures to poisonous substances (Figure 16-10 ■). Poisonous inhalation injury is an umbrella label for any type of inhalation injury that occurs secondary to exposure to toxic substances that can cause airway occlusion and/or pulmonary dysfunction by inhibiting the normal exchange of gases at the cellular level. For example, a patient may be exposed to a volatile chemical through an industrial accident, and this chemical could cause airway edema, alveolar lining damage, or displacement of oxygen. Any of these can result in respiratory failure and death of the patient unless there is immediate and effective treatment.

**Pathophysiology.** The inhalation of any vapors or fumes has the potential for causing some type of compromise to the patient. The majority of toxic inhalation injuries, as will be discussed in Chapter 22, “Toxicologic Emergencies,” occur as the result of a fire. Sometimes, though, the toxic exposure may not be evident, since fumes may be present in the environment but undetected by the patient. The first indication of a toxic or poisonous inhalation exposure may be the patient’s collapse.

Commonly inhaled poisons that the EMT may be called on to treat include:
• Carbon monoxide
• Cyanide
• Natural gas
• Chlorine gas
• Liquid chemicals or sprays
• Ammonia
• Sulfur dioxide
• Anesthetic gases
• Solvents
• Industrial gases
• Hydrogen sulfide
• Fumes/smoke from fires
• Paints or Freon
• Glue (Toluene)
• Nitrous oxide
• Amyl or butyl nitrate

These substances can have many effects on the body, as they all lead to cellular hypoxia by some mechanism. They may cause the soft tissue that lines the upper airway to swell to the point that airway occlusion occurs. Some can also cause the displacement of oxygen in the atmosphere and, hence, in the alveoli, also causing hypoxia. The chemicals may be caustic to the point that the alveolar lining is damaged and fluid starts to leak into the alveoli, severely hampering gas exchange. And finally, some inhaled poisons may also exert an action on the body in and of themselves once they cross into the bloodstream. The end result of all these mechanisms, if treatment is delayed, is inadequate cellular respiration, causing cellular death and, in turn, the death of the patient.
Assessment. Signs and symptoms of poisonous inhalation injuries are as follows:

- History consistent with an inhalation injury (house fire, industrial accident, and so on)
- The presence of chemicals about the face from the exposure
- Findings of respiratory distress (consistent with either adequate or inadequate breathing)
- Cough, stridor, wheezing, or crackles
- Oral or pharyngeal burns, possible hoarseness
- Dizziness, feelings of malaise
- Headache, confusion, altered mental status
- Seizures
- Cyanosis or other skin color changes
- Nausea, vomiting, abdominal distress/pain
- Copious secretions
- Vital sign changes

ASSESSMENT TIPS

Among the most important determinants for patient criticality is the length of exposure to the toxic substance and whether the patient was in an enclosed space. Additionally, exercise great personal caution when entering the scene of a known or potential toxic inhalation unless you are properly trained to do so and protected (i.e., wearing SCBA).

Emergency Medical Care. Remember that symptoms of respiratory distress are among the most common initial findings consistent with toxic inhalation injuries. The most important primary treatment is to limit the exposure if the patient is still in the toxic environment. Be sure, however, that you can rescue the patient in a manner that is not dangerous to you. If you can’t effect a rescue safely, your best action is to remain at a safe distance until properly trained and equipped providers can bring the patient to you.

After ensuring that there is no threat to you, your next goal is to ensure an open airway. If the patient is able to maintain his own airway and there is no associated trauma, place him in a position of comfort. If he is traumatized or unresponsive, place the patient supine and immobilize as needed. Maximize oxygenation for the adequately breathing patient by providing oxygen at 15 lpm via nonrebreather mask. If you find the patient is breathing inadequately, provide positive pressure ventilation at a rate of 15 lpm per minute in the adult patient with supplemental oxygen attached. Be sure to properly treat any other injuries or abnormal findings, after ensuring that any compromises to the airway, breathing, and circulatory components are appropriately managed.

Prior to transport, try to ascertain as much information as possible about the inhaled poison for the receiving facility. Because of the criticality of the patient or the potential for rapid deterioration, try to arrange an ALS intercept en route to the receiving facility. Provide early notification to the staff at the receiving facility so they can prepare adequately for your arrival.

Viral Respiratory Infections

As its name indicates, a viral respiratory infection (VRI) is a condition of the respiratory system caused by a virus. Common VRIs include bronchiolitis, colds, and the flu. In most situations for adults, VRIs are fairly mild, self-limiting, and confined to the upper respiratory system. In children, however, the infection has a greater propensity to spread into the lower airways where more significant infections can occur that will result in patient deterioration.

Pathophysiology. Viral respiratory infections are commonly referred to as upper respiratory infections (URIs) by the medical community because the majority of symptoms are found in the nose and throat. In small children, however, VRIs can also cause infections of the lower airway structures such as the trachea, bronchi, bronchioles, or lungs. When an infection involves these lower airway structures, depending on site, the patient may be diagnosed with croup, bronchiolitis, or pneumonia. (See Chapter 38, “Pediatrics,” for a discussion of these conditions.)

Known viruses that can cause VRIs include rhinoviruses, parainfluenza and influenza viruses, enteroviruses, respiratory syncytial virus (RSV), and some strains of the adenovirus. These viruses gain entry into the body by way of patient-to-patient contact or, to a lesser extent, through inhalation of respiratory droplets. The major pathophysiology of these viruses is exerted by triggering an inflammatory process with increased mucus production to the upper respiratory structures. There may also be a fever associated with the infection, coughing, runny nose, and findings of mild respiratory distress in the majority of cases. The VRI typically runs its course in about 14 days and, unless extenuating circumstances are present (e.g., a secondary respiratory infection of the lower airways or severe respiratory distress), rarely requires medical attention.

Assessment. It is, of course, nearly impossible (nor is it practical) for the EMT to determine if findings of respiratory distress are caused by a VRI or not. There are also no specific treatments for viral infections that the EMT can administer. The mainstay of emergency treatment for respiratory distress secondary to a VRI is supportive.

The following are signs and symptoms of viral respiratory infections:

- Nasal congestion
- Sore or scratchy throat
- Mild respiratory distress, coughing
- Fever (usually around 101°F–102°F)
- Malaise
- Headaches and body aches
- Irritability in infants and poor feeding habits
- Tachypnea
- Exacerbation of asthma if patient is asthmatic
Emergency Medical Care. The majority of cases of VRI do not present to EMS because the clinical presentation is confined to nasal and pharyngeal discomfort. In the susceptible patient, however, there may be the presence of concurrent lower tract infections that can cause some degree of respiratory distress. In all but the most severe (and uncommon) cases, supportive treatment of positioning, oxygen therapy, emotional support, and gentle transport to the hospital is all that is necessary.

If the infection is allowed to persist without medical attention and it develops into a more serious viral infection (especially for the very young or very old), supplemental oxygen and, occasionally, mechanical ventilation may become warranted. Despite the often minimal presentation, the EMT should always maintain a high index of suspicion for deterioration in a patient who does not respond favorably to supportive measures. As needed, contact ALS for potential medication administration.

Using a Metered-Dose Inhaler

The MDI, also known as an “inhaler” or “puffer,” is a simple device that consists of a metal canister and a plastic container with a mouthpiece and cap. The metal canister contains the medication that fits inside the plastic container. When the canister is depressed, it delivers a precise dose of medication to the patient to inhale. The medication is directly deposited on the bronchioles at the site of bronchoconstriction. See the photos in EMT Skills 16-2, which illustrate administering a medication by MDI.

Some MDIs are connected to a device called a spacer. The spacer is a chamber that holds the medication until it is inhaled, thus preventing any loss of medication to the outside and allowing a greater amount of the medication to be delivered to the patient. The spacer device is commonly used by patients who have difficulty using the MDI and is a very effective method of delivering the medication. Spacers are increasingly common as a standard in MDI administration. See the photos in EMT Skills 16-3, which illustrate how to administer an MDI with a spacer.

If the patient is having breathing difficulty that is not related to trauma or a chest injury, and has one of the beta2 agonist bronchodilators in an MDI form prescribed to him by a physician, you should contact medical direction for permission to administer the drug or follow local protocols. Instruct your patient as to what he should do, even if he claims to know how to use the MDI. During the administration, you must coach the patient to breathe in slowly and deeply, to hold his breath as long as he comfortably can, and to breathe out slowly through pursed lips. If the patient is not instructed or coached, the medication may not be effectively administered. If the patient is unable to follow the procedure, even with coaching, you may need to administer the inhaler to the patient. Table 16-4 lists a series of “dos and don’ts” for administering medication from MDIs.

Using a Small-Volume Nebulizer

Some patients who are prescribed beta2 agonists may use a small-volume nebulizer rather than a metered-dose inhaler to dispense the medication. An SVN is a device that has a drug reservoir into which the patient
Metered-Dose Inhaler (MDI)/Small-Volume Nebulizer (SVN)

Medication Name
Metered-dose inhalers contain medications with a variety of generic and trade names, including the following. (Note: Not all drugs that are packaged as an MDI are available for nebulization.)

<table>
<thead>

</tbody>
</table>

Indications
All of the following criteria must be met before an EMT administers a bronchodilator by metered-dose inhaler (MDI) or small-volume nebulizer (SVN) to a patient:
- The patient exhibits signs and symptoms of breathing difficulty (respiratory distress).
- The patient has a physician-prescribed metered-dose inhaler containing a medication specifically prepared to be delivered by nebulization.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

Contraindications
A bronchodilator by MDI or SVN should not be given if any of the following conditions exist:
- The patient is not responsive enough to use the MDI or SVN.
- The MDI or SVN is not prescribed for the patient.
- Medical direction has not granted permission.
- The patient has already taken the maximum allowed dose(s) prior to your arrival.

Medication Forms
Aerosolized medication in an MDI. Liquid medication packaged to be poured directly into the nebulizer chamber of an SVN (see EMT Skills 16-4C).

Dosage
Each time an MDI is depressed, it delivers a precise dose of medication to the patient. The total number of times the medication can be administered is determined by medical direction. When using an SVN, it usually takes 5–10 minutes for the patient to inhale the medication, depending on the rate and depth of breathing. The medication should be inhaled until the SVN no longer produces a mist.

Administration
To administer a bronchodilator by MDI (EMT Skills 16-2):
1. Ensure right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the inhaler and if any doses have already been administered prior to your arrival.
2. Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication.
3. Ensure that the inhaler is at room temperature or warmer. Shake the canister vigorously for at least 30 seconds.
4. Remove the nonrebreather mask from the patient. Instruct the patient to take the inhaler in his hand...

continued
and hold it upright. If the patient is unable to hold the device, place your index finger on top of the metal canister and your thumb on the bottom of the plastic container.

5. Have the patient exhale fully.

6. Have the patient place his lips around the mouthpiece (opening) of the inhaler. Another technique is to have the patient open his mouth and place the inhaler 1–1.5 inches from the front of the lips, estimated by two finger widths.

7. Have the patient begin to slowly and deeply inhale over about 5 seconds as he or she depresses the canister. Do not depress the canister before the patient begins to inhale. This would allow a majority of the medication to be lost into the air and it will not reach the lower respiratory tract.

8. Remove the inhaler and coach the patient to hold his breath for 10 seconds or as long as comfortable.

9. Have the patient exhale slowly through pursed lips.

10. Replace the oxygen mask on the patient. Reassess the breathing status and baseline vital signs.

11. Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the medication being administered or medical direction’s order.

If using a spacer, follow the same steps with the following exceptions for steps 6 and 7 (EMT Skills 16-3):

6. Remove the spacer cap and attach the inhaler to the spacer.

7. Depress the medication canister to fill the spacer with the medication. As soon as the canister is depressed, have the patient place his lips around the mouthpiece and inhale slowly and deeply. If the inhalation is too fast, the spacer may whistle.

To administer a bronchodilator by SVN (EMT Skills 16-4):

1. Ensure right patient, right medication, right dose, right route, and right date. Determine if the patient is alert enough to use the nebulizer and if any doses have already been administered prior to your arrival.

2. Obtain an order, either on-line or off-line, from medical direction to assist with the administration of the medication.

3. Disassemble the medication chamber from the mouthpiece by unscrewing it. While holding the medication reservoir upright, pour in the medication and reassemble the device.

4. Attach the tubing extending from the bottom of the drug reservoir to the nebulizer compressor and turn it on, or attach the tubing to an oxygen tank with the liter flow set to 8–10 lpm. You should note the mist coming from the mouthpiece almost immediately.

5. Remove the nonbreather mask from the patient. Instruct the patient to take the nebulizer in his hand and hold it upright. If the patient is unable to hold the device, you may have to do this for the patient, being sure to continuously hold it upright for optimal nebulization of the medication.

6. Have the patient exhale fully.

7. Instruct the patient to place his lips around the mouthpiece of the nebulizer. Another technique is to have the patient open his mouth and place the mouthpiece 1–1.5 inches from the front of the lips, estimated by two finger widths.

8. Have the patient begin to slowly and deeply breathe in the mist.

9. Instruct the patient to occasionally (every 2–3 breaths) hold his breath after inhalation as long as he comfortably can, to assist with medication distribution throughout the respiratory tree.

10. Have the patient exhale normally, and occasionally (every 2–3 breaths) instruct the patient to cough during exhalation to facilitate removal of any mucus or secretions that may be present.

11. You may need to occasionally shake the nebulizer to dislodge any medication that tends to collect on the sides of the drug reservoir. In about 5–10 minutes, the misting of medication should cease and the liquid medication you placed in the nebulizer will be gone. Replace the oxygen mask on the patient.

12. Reassess the patient and consult with medical direction if additional doses are needed. If an additional dose is recommended, wait at least 2 minutes between each administration or longer based on the medication being administered or medical direction’s order.

**Actions**

Beta 2 agonist that relaxes the bronchile smooth muscle and dilates the lower airways. This reduces the airway resistance and improves airflow into the alveoli.

**Side Effects**

The side effects associated with the bronchodilator are associated with the drug action itself. The following are common side effects that the patient may complain of or that you may find in your assessment:

- Tachycardia
- Tremors, shakiness
- Nervousness
- Dry mouth
- Nausea, vomiting
Reassessment
Whenever you administer a bronchodilator to a patient, you must perform a reassessment. The following steps must be included:

- Reassess the vital signs.
- Question the patient about the effect of the medication on the relief of the difficulty in breathing.
- Perform a focused physical exam if changes in the condition or new complaints occur.
- Constantly monitor the airway and breathing status; if the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.
- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.

Selected Publishing Services

Metered-Dose Inhaler (MDI)/Small-Volume Nebulizer (SVN)

Reassessment
Whenever you administer a bronchodilator to a patient, you must perform a reassessment. The following steps must be included:

- Reassess the vital signs.
- Question the patient about the effect of the medication on the relief of the difficulty in breathing.
- Perform a focused physical exam if changes in the condition or new complaints occur.
- Constantly monitor the airway and breathing status; if the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.
- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.

**TABLE 16-4  MDI Administration Dos and Don’ts**

When administering a metered-dose inhaler, follow these tips:

**Do**
- Instruct the patient to breathe in slowly and deeply.
- Be sure the patient is breathing in through his mouth.
- Shake the canister for at least 30 seconds before removing the cap.
- Depress the canister as the patient begins to inhale.
- Coach the patient to hold his breath as long as possible.
- Use a spacer device if available and the patient is used to it.

**Don’t**
- Allow the patient to breathe in too quickly.
- Allow the patient to breathe in through his nose.
- Administer the medication before shaking the canister.
- Depress the canister before the patient begins to inhale.
- Forget to coach the patient to hold his breath as long as possible.
- The patient may experience a variety of side effects from the medication. The most common are an increased heart rate, tremors, and nervousness. More detailed information about bronchodilators and other side effects are listed in Figure 16-11.

Advair: Not for Emergency Use
A drug that is commonly prescribed for patients with uncontrolled asthma is the Advair Diskus (Figure 16-12). Unlike the short-acting beta₂ agonists (for example, albuterol, Xopenex, Bronkosol) that are delivered via an MDI or SVN, Advair is a long-acting beta₂-specific drug (salmeterol xinafoate) that also contains a steroid (fluticasone propionate) that is used as a maintenance drug. The drug comes in a rotodisk or discus delivery device that requires a different method of administration than the MDI or SVN. Even though Advair is used to treat asthma, it is not to be used as a rescue inhaler for the patient experiencing an acute asthma attack. Only
a short-acting beta2-agonist drug as listed in Figure 16-11 should be used in the emergency care of the patient experiencing an acute asthma attack.

**AGE-RELATED VARIATIONS: PEDIATRICS AND GERIATRICS**

In almost all emergency situations, the EMT must remain acutely aware of idiosyncrasies of patients at both age extremes, the very young and the very old. The incidence and presentation of respiratory disorders in the pediatric patient can be unique because of the differences in anatomy and physiology; similarly, the changes that occur to the anatomy and physiology of the body during aging can alter the incidence and presentation of respiratory distress in the geriatric patient. The goal of the following section is to introduce some of the idiosyncrasies that may be present in patients at the age extremes.

**Pediatric Patients**

Since infants and children generally have healthy hearts, respiratory failure is the most likely cause of both respiratory arrest and cardiac arrest. This may be prevented if you can recognize the early signs of respiratory distress or respiratory failure and provide the appropriate emergency care.

Respiratory failure for the pediatric patient is defined as inadequate oxygenation of the blood and an inadequate elimination of carbon dioxide from the body. It is usually the result of an inadequate respiratory rate and/or inadequate tidal volume, either of which constitutes inadequate breathing and can lead to respiratory arrest. The root cause is most likely either an upper airway blockage or a lower airway disease. Respiratory conditions in infants and children are discussed in more detail in Chapter 38, “Pediatrics.”

**Respiratory Distress in the Pediatric Patient: Assessment and Care**

Dispatch to an emergency involving an infant or child may provide indications that the patient is suffering from respiratory distress or failure. The time it takes you to arrive at the patient’s location should be used to mentally process the points discussed in this section.

**Scene Size-up and Primary Assessment**

During scene size-up with the infant or child, as with the adult patient, look for clues to help rule out trauma as a cause of the problem.

Many of the signs and symptoms of breathing difficulty can be spotted as you form your general impression during the primary assessment. Labored or noisy breathing, and a child who is sitting up in a tripod position, lying limply, or unresponsive can be detected “from the doorway,” even before you approach the patient. Additional signs and symptoms will be discovered as you contact the infant or child to assess mental status, airway, breathing, and circulation.

**Secondary Assessment**

Other signs and symptoms may be noted during the secondary assessment of the young patient. (Assessing the infant or child patient will be covered in detail in Chapter 38, “Pediatrics.”) Typically, signs and symptoms of respiratory distress will precede respiratory failure in the infant or child. These signs and symptoms will be indications that the body is attempting to compensate for the poor oxygen and carbon dioxide exchange by increasing the work of breathing.

**Early Signs of Breathing Difficulty (Respiratory Distress) in the Infant or Child.** Because respiratory distress may quickly proceed to respiratory failure in the infant or child, it is vital that you recognize any of these early signs of breathing difficulty:

- Increased use of accessory muscles to breathe
- Sternal and intercostal retractions during inspiration
- Tachypnea (increased breathing rate)
- Tachycardia (increased heart rate)
- Nasal flaring
- Prolonged exhalation
- Frequent coughing—may be present rather than wheezing in some children
- Cyanosis to the extremities
- Anxiety

The chest wall is extremely pliable in infants and young children, and the intercostal muscles (muscles between the ribs) are not well developed. Therefore, the child relies heavily on the diaphragm and abdominal muscles to breathe and does not rely very much on the intercostal muscles. Obvious abdominal movement is expected during normal breathing in an infant or young child. In a sense, the intercostal muscles in the infant and young child are viewed more as accessory muscles to breathing. Thus, in the infant and young child, retractions appear to be more prominent early in respiratory distress when they begin to use the...
intercostal muscles to assist in breathing. This is very different from the adult who has a stiffer chest and well-developed intercostal muscles. Retractions in an adult respiratory distress patient are a significant sign of severe respiratory distress.

Signs of Inadequate Breathing (Respiratory Failure) in the Infant or Child. Signs of respiratory failure, which may be similar to those of inadequate breathing, are an indication that the cells are not receiving an adequate oxygen supply. Respiratory compromise, leading to the need to provide positive pressure ventilation, should be recognized in patients who have signs and symptoms of respiratory distress with increased efforts to breathe who continue to deteriorate, or in patients who have inadequate respiratory effort, even with no signs or symptoms of distress.

Respiratory arrest is a condition with no respirations or respiratory effort; however, a pulse is still present. The signs listed here occur late in a respiratory emergency and are an indication that you must immediately intervene and begin positive pressure ventilation with supplemental oxygen:

- Altered mental status—the patient may be listless or completely unresponsive
- Bradycardia (slow heart rate) (Bradycardia would be an initial response in a newborn, a late response in an infant.)
- Hypotension (low blood pressure)
- Extremely fast, slow, or irregular breathing pattern
- Cyanosis to the core of the body and mucous membranes—a late and inconsistent sign
- Loss of muscle tone (limp appearance)
- Diminished or absent breath sounds
- Head bobbing—bobbing of the head with each breath
- Grunting—heard in infants and children during exhalation, indicating diseases that produce lung collapse
- Seesaw or rocky breathing—the chest is drawn inward and the abdomen moves outward, indicating extreme inspiratory efforts
- Decreased response to pain
- Inadequate tidal volume (poor chest rise and fall)

Emergency Medical Care

The emergency medical care for the infant and child is similar to that for the adult. Your goal should be to promptly and efficiently care for the infant or child and minimize the amount of stress. An increased stress level will increase the work of breathing and the body’s oxygen demand. Because of the danger that respiratory distress will deteriorate into respiratory failure, prompt intervention and transport is especially critical for the infant or child.

For a child who is experiencing difficulty in breathing with adequate breathing (respiratory distress), take the following steps:

1. Allow the child to assume a position of comfort to reduce the work of breathing and to maintain a more patent airway. Do not remove the infant or child from his parent (or other caretaker). Allowing the parent to hold the child will reduce the apprehension and stress levels, thereby reducing the breathing work load and oxygen demand.
2. Apply supplemental oxygen to a child who is sitting up in his parent’s lap. If the child does not tolerate an oxygen mask, have the parent hold it near the child’s face (Figure 16-13). 
3. If at any time the infant or child’s breathing becomes inadequate (respiratory failure), remove him from the parent, establish an open airway, and begin positive pressure ventilation with supplemental oxygen. It will be necessary to repeat the physical exam and vital signs.

Just as with adults, a child may also have an MDI or SVN prescribed for respiratory problems associated with the lower airway. These children may present with audible wheezing; diminished breath sounds bilaterally; pale, cool, clammy skin; cyanosis; poor chest rise and fall; and other signs of breathing difficulty. If the child is experiencing breathing difficulty and has a prescribed inhaler or nebulizer, follow the same emergency care procedures for administration of the medication via MDI or SVN as for the adult.

It is important to bear in mind that the upper airway can be obstructed by foreign bodies or from swelling associated with certain diseases, medical conditions, burns, or toxic inhalations. Stridor and crowing are typical sounds made when the upper airway is partially obstructed by a foreign body or swelling. If a foreign body obstruction is suspected, and the airway is completely blocked, perform foreign body airway obstruction (FBAO) maneuvers to attempt to relieve the obstruction. (Refer to Chapter 38, “Pediatrics,” to review these techniques for the infant and child.) If the airway is partially blocked, place the patient on a nonrebreather mask at 15 lpm and immediately begin transport. Be
alert to begin FBAO maneuvers if the partial obstruction becomes complete.

It is important to distinguish blockage caused by a foreign body in the airway from blockage caused by disease. FBAO maneuvers may involve inserting suction devices or the fingers into the airway to remove foreign materials. With some airway diseases, inserting anything into the airway will cause dangerous spasms along the airway, making the condition worse.

Croup (laryngotraeobronchitis), commonly seen in children, involves the swelling of the larynx, trachea, and bronchi, causing breathing difficulty. The child typically does not feel well, has a sore or hoarse throat, and has a fever. At night, the condition usually worsens. You might hear a hallmark sign of croup, a cough that sounds like a barking seal. Provide oxygen to the patient, humidified if possible, and begin transport. Usually cool night air will reduce the signs and symptoms somewhat; therefore, the condition may subside slightly after the child is taken outside for transfer to the ambulance. Inadequate breathing can result from croup, so continuously monitor the breathing status.

Gathering a history is especially important when airway blockage is suspected, since it may identify either preexisting diseases that may be causing the airway closure or events that may have led to a foreign body obstruction. (For example, someone witnessed the child choking on food or saw the child put an object into his mouth, or there were small objects around the child that he could have swallowed.) If the blockage was sudden and there was something around that the child could have swallowed and there is no history or other sign of disease, treat the patient for an upper airway foreign body obstruction. If the blockage came on gradually, the child has other signs of being ill, or the child has a history of respiratory or other disease, and no one saw the child swallow anything, avoid inserting anything into the airway. Instead, provide oxygen or positive pressure ventilation with supplemental oxygen as necessary.

**Reassessment**

Transport any infant or child with difficulty breathing or signs of inadequate breathing or airway blockage. Provide reassessment en route. Be prepared to intervene more aggressively if the condition deteriorates.

**Geriatric Patients**

Respiratory distress can result from any of a number of conditions occurring in the geriatric patient. It can be the primary symptom of a pulmonary problem, or it can be a symptom secondary to failure of a different body system (congestive heart failure, for example, can cause difficulty in breathing). Therefore, difficulty breathing or “shortness of breath” (dyspnea) is one of the more common complaints noted in the elderly. It is important to realize that the elderly already have diminished respiratory function. Therefore, any additional burden can easily overwhelm the respiratory system and lead to inadequate breathing.

**Respiratory Distress in the Geriatric Patient: Assessment and Care**

The EMT may have indication that the geriatric patient is suffering from respiratory distress or failure from information received by dispatch. Hints could include the known presence of dyspnea by the caller, but it may also be manifested in complaints such as weakness, inability to ambulate, confusion, chest/abdominal pain, or falls. The time it takes you to arrive at the patient’s location should be used to mentally process the points discussed in this section.

**Scene Size-up and Primary Assessment**

During scene-size up with the geriatric patient, look for clues to help rule out trauma as a cause of the problem. Many of the signs and symptoms of breathing difficulty can be spotted as you form your general impression during the primary assessment. Labored or noisy breathing, a patient in a tripod position, a patient lying in bed with multiple pillows behind his head, or unresponsiveness can be detected even before you approach the patient. Additional signs and symptoms will be discovered as you contact the patient to assess mental status, airway, breathing, and circulation.

**Secondary Assessment**

Other signs and symptoms may be noted during the secondary assessment of the geriatric patient. (Assessing the geriatric patient will be covered in detail in Chapter 39, “Geriatrics.”) The geriatric patient may not exhibit the typical response to hypoxia and hypercapnea; additionally, this patient may not develop fever in response to infection. The signs and symptoms of respiratory distress usually briefly precede respiratory failure in geriatric patients. Older patients do not have the compensatory mechanisms a younger adult has, and they typically decompensate much more rapidly. Whenever you see indications of respiratory distress, remember that these indicate the body is attempting to compensate for the poor oxygen and carbon dioxide exchange by increasing the work of breathing, but this compensatory mechanism may be short-lived.

**Early Signs of Breathing Difficulty (Respiratory Distress) in the Geriatric Patient.** Because respiratory distress may quickly proceed to respiratory failure in the geriatric patient, it is vital that you recognize these early signs of breathing difficulty:

- Increased use of accessory muscles to breathe
- Sternal and intercostal retractions during inspiration
Emergency Medical Care

The emergency medical care for the geriatric patient is similar to that for the adult. Your first goal should be to reduce any anxiety or stress the patient is experiencing. An increased stress level will increase the work of breathing and the body’s oxygen demand. Because of the danger that respiratory distress will deteriorate into respiratory failure, prompt intervention and transport is especially critical.

For a geriatric patient who is experiencing difficulty in breathing with adequate breathing (respiratory distress), take the following steps:

1. Place the patient in a position of comfort to reduce the breathing work and maintain a more patent airway. Typically this will be a sitting-up position to help the respiratory muscles work more efficiently.
2. Administer supplemental oxygen to maintain an SpO₂ of ≥94%.
3. If at any time the patient’s breathing becomes inadequate (respiratory failure), lay him down flat, establish an open airway, and begin positive pressure ventilation with supplemental oxygen. It will be necessary to repeat the physical exam and vital signs.

Reassessment

Transport any geriatric patient with difficulty breathing or signs of inadequate breathing. Provide reassessment en route. Be prepared to intervene more aggressively if the condition deteriorates.

ASSESSMENT AND CARE: GENERAL GUIDELINES

Assessment-Based Approach: Respiratory Distress

Information provided by the dispatcher may be the first indication that a patient is suffering from a respiratory emergency. The information that the patient is complaining of breathing difficulty should heighten your suspicion of a potential respiratory problem.

Scene Size-up

Seek clues to determine whether the breathing difficulty is due to trauma or to a medical condition. Be careful not to develop tunnel vision and miss important indications of alternative causes for the breathing difficulty that are not the result of a respiratory problem—for example, a cardiac problem or an open chest wound.

Scan the scene for possible mechanisms of injury. Bystanders who heard gunshots, saw a knife, or heard loud fighting may indicate that the patient’s difficulty in
breathing may be trauma related. The patient who is found in his house in the middle of the living room may have fallen, struck his chest against the coffee table, and fractured some ribs, causing the lung to collapse. A tall, lanky male patient may have been moving a heavy object or coughing when he experienced a sudden onset of shortness of breath that progressively worsened. Look for oxygen tanks, oxygen tubing, or oxygen concentrators, or medication inhalers or nebulizers at the scene. They usually indicate a chronic respiratory disease. Also scan the scene for alcohol, which is a common contributor to choking and upper airway obstruction and aspiration of vomitus.

**Primary Assessment**

Form a general impression and assess the mental status, airway, breathing, and circulation.

**General Impression.** Several clues can help you form an impression of a patient who is suffering respiratory distress. These include:

- **The patient’s position.** Most frequently, in severe cases of respiratory distress, patients sit upright and lean slightly forward, supporting themselves with their arms, elbows locked in place in front of them between their dangling legs, holding onto the seat. This is referred to as a **tripod position** (Figure 16-14 ■).

  The patient in a reclining or supine position could indicate two possible scenarios: (1) the patient is only in mild distress, or (2) the patient is in such severe respiratory distress that he is too exhausted from trying to breathe to hold himself up. This patient requires immediate intervention since respiratory arrest usually follows shortly after development of severe fatigue.

- **The patient’s face.** An agitated or confused facial expression may indicate inadequate breathing, hypoxia, or hypercarbia.

- **The patient’s speech.** If the speech is normal, assume that the airway is open and clear and the distress is minimal. If the patient is alert and makes eye contact but is unable to speak, consider a severe condition. The patient may speak one or two words and then pause to gasp for a breath. The number of words the patient can speak during one breath usually correlates with the severity of the breathing difficulty.

- **Altered mental status.** A change in the mental status, such as confusion, is a clear indication of inadequate oxygenation of the brain (cerebral hypoxia) and a buildup of carbon dioxide. A sign of imminent respiratory failure is when the patient’s eyelids begin to droop and the head bobs with each respiration, as if the patient is beginning to fall asleep while sitting upright. This is a sign that the patient needs positive pressure ventilation immediately.

- **Use of the muscles in the neck and retractions of the muscles between the ribs (intercostal muscles).** Accessory muscle use and retractions are an indication of a significant increased inhalation effort with each breath.

- **Cyanosis.** Cyanosis (bluish gray skin color) is a clear indication of hypoxia but also a sign that may occur late. Look at the area around the nose and mouth when getting the general impression. You will examine many other areas for cyanosis in the physical exam.

- **Diaphoresis.** A patient with respiratory distress commonly is diaphoretic (having sweaty and moist skin that is inappropriate for the temperature or activity). The patient becomes more diaphoretic the harder he works to breathe.
• **Pallor.** Pale skin color is a sign of hypoxia and severe respiratory distress. Pallor will be seen earlier and more often than cyanosis.

### ASSESSMENT TIPS

Pale, cool, clammy skin is an early sign of hypoxia in the patient. Cyanosis is a clear but late sign of hypoxia.

• **Nasal flaring.** Flaring of the nostrils with inhalation is another indication that the patient is working hard to breathe in.

• **Pursed lips.** Pursed-lip breathing is when the patient puts his lips together during exhalation as if he is going to whistle. Patients with some chronic respiratory diseases do this subconsciously. This is done to keep the airway pressure in the smaller bronchioles higher during exhalation so they don’t collapse but remain open, making the next inhalation a little easier.

**Mental Status.** Restlessness, agitation, confusion, and unresponsiveness are frequently associated with breathing difficulty because the brain is not getting enough oxygen.

**Airway.** Assess the airway for any indication of a complete or partial obstruction from secretions, blood, vomitus, or a foreign body. Listen for snoring, stridor, gurgling, or crowing. Each indicates partial airway obstruction. However, keep in mind that obstructed breathing is not always noisy. Clear the airway with suction, manual maneuvers, and airway adjuncts as needed.

**Breathing.** Carefully assess the breathing. Look at the chest rise and fall, listen and feel for air flowing in and out of the mouth and nose, and quickly auscultate the lungs. Be aware of a chest that is moving up and down upon inspection but produces very little or no air movement from the mouth and nose. Efforts to breathe are being made but are not effective. This patient needs positive pressure ventilation with supplemental oxygen no matter how well the chest is rising and falling. Auscultate the breath sounds on both sides of the chest. Absent or diminished breath sounds are an indication that very little air is moving in and out of the lungs.

Determine an approximate respiratory rate. *If the chest is not rising adequately with each breath or you do not hear or feel an adequate volume of air escaping on exhalation, begin positive pressure ventilation with supplemental oxygen.*

Look for respiratory rates outside the ranges of 8–24 breaths per minute for adults, 15–30 per minute for children, and 25–50 per minute for infants. A respiratory rate that is too slow will not allow enough air to be transported to the alveoli for adequate gas exchange, leading to hypoxia. This patient must be provided positive pressure ventilation.

### ASSESSMENT TIPS

The average range of normal respiration for an adult patient is 12–20 breaths per minute; however, it is possible for the patient with lower or higher rates to be breathing adequately. Look at the entire patient and assess the tidal volume closely. If the tidal volume (assess chest rise and air movement) is inadequate in high rates, immediately begin ventilation. Elderly patients will have higher resting respiratory rates, typically 20 per minute.

On the other hand, a respiratory rate that is too fast does not always compensate for a poor volume of air the patient is breathing. In many cases, the respiratory rate becomes so fast (adult > 40/minute, infant > 60/minute) that it does not allow the patient to take a full enough breath before having to exhale, leading to ineffective volumes of air during inhalation. The respiratory rate will appear faster than normal; however, the chest will not rise adequately or very little air movement will be felt. You must immediately begin positive pressure ventilation. The inadequate chest rise and fall or little movement of air is commonly referred to as shallow breathing. *Shallow breathing is an indication of inadequate breathing.*

In order to have adequate breathing, you must have both an adequate rate and an adequate tidal volume (amount of air moving in and out with one breath). If either the rate or the tidal volume is inadequate, the patient must be provided positive pressure ventilation. If both the rate and the tidal volume are inadequate, you must provide positive pressure ventilation. If the rate and tidal volume are both adequate, you can administer oxygen to maintain an SpO₂ of ≥94%.

You must be aggressive when managing the airway and ventilation status of the patient. Remember that any indication of poor or inadequate ventilation must be managed with positive pressure ventilation.

During your assessment, you can summarize the patient’s respiratory status as follows:

- **One inadequate** (either rate or tidal volume) = inadequate breathing.
- **Two inadequates** (both rate and tidal volume) = inadequate breathing.
- **Two adequates** (both rate and tidal volume) = adequate breathing.

Remember that a patient who complains of breathing difficulty or presents with signs of hypoxia or hypercarbia may have either adequate or inadequate breathing, as just defined. The patient with inadequate breathing will be treated differently from the patient with adequate breathing, as follows:

- **Inadequate breathing**—Provide positive pressure ventilation with a bag-valve mask or pocket mask with oxygen connected to the device.
- **Adequate breathing**—Administer oxygen to maintain an SpO₂ of ≥94% (Figure 16-15 ▼).
Circulation. Inspect the patient’s skin and mucous membranes. Cyanosis, or bluish gray skin, especially to the face, lips, neck, and chest, is an ominous sign of respiratory distress. In people with dark skin, check for cyanosis of mucous membranes under the tongue, at the lining of the mouth, or to the inside of the lower eyelid (conjunctiva). Tachycardia and pale, cool, moist skin are also signs of respiratory distress and hypoxia.

Priority. Because a patient with difficulty in breathing is considered a priority patient, consider advanced life support backup and expeditious transport. In the patient with severe respiratory distress, respiratory failure, or respiratory arrest, you will want to transport as soon as possible and continue your secondary assessment en route to the hospital. Signs that you may need to transport expeditiously are evidence of inadequate breathing, an irregular pulse or increased pulse rate (tachycardia) in adults and children, a slow pulse (bradycardia) in newborns with breathing difficulty, and an altered mental status. Also, as stated earlier, cyanosis is an ominous and late sign of respiratory distress, as is a very slow respiratory rate.

Secondary Assessment

If the patient is responsive, obtain a history using the OPQRST questions to evaluate the history of the present illness (Table 16-5). If the patient is unresponsive, perform a rapid physical exam and collect as much information as possible from any family or bystanders at the scene.

History. The following questions will be particularly helpful in determining your emergency care steps for a patient with respiratory distress:

- Does the patient have any known allergies to medications or other substances that may be related to the episode of difficulty in breathing? For instance, some patients may experience a sudden onset of breathing difficulty when they have inhaled substances like dust, dog hair, cat hair, mold, or irritating smoke. An extreme allergic reaction (anaphylaxis), for example, to a bee sting or to something the patient has eaten will cause swelling of the tissues of the upper airway, bronchospasm, and severe respiratory distress.
- What medications, prescription or nonprescription, is the patient taking? Gather them to take to the hospital. As discussed earlier, metered-dose inhalers and small-volume nebulizers are devices that are used to deliver a medication by inhalation. These devices are frequently used by patients with a chronic respiratory condition.

disease or recurring breathing problems. Occasionally you might find oral medications used specifically for respiratory problems. Common medications that might be found on the patient or at the scene are found in Table 16-6. It is important to recognize these since they might provide you with a clue that the patient has a history of respiratory problems, and medical direction may instruct you to administer one of them. Ask if the patient has already taken any of the medications prior to your arrival, and if so, how many times. Report this information to medical direction or the receiving hospital.

Note: Medications used by patients with chronic respiratory disease have a variety of side effects. Because many patients self-administer their medication prior to your arrival, this may confuse your assessment slightly since the signs and symptoms now exhibited may result from the medication and not necessarily from the respiratory condition. These side effects are also listed in Table 16-6.

- Does the patient have a preexisting respiratory or cardiac disease?
- Has the patient ever been hospitalized for a chronic condition that produces recurring episodes of difficulty in breathing? If so, did he have an endotracheal tube placed down his throat to breathe or require admission to an intensive care unit? This usually indicates that the patient may have a tendency to deteriorate much more rapidly and may require quicker and more aggressive intervention.

Physical Exam. The physical exam will give you further information that may indicate the severity of the breathing distress and help you determine whether to simply apply high-concentration oxygen by non-rebreather mask or to proceed with positive pressure ventilation with supplemental oxygen. If the patient is unresponsive, perform a rapid assessment. In the responsive patient, focus the exam on the areas that might provide you with clues as to the severity of the condition.

The posture of the patient is important. As the patient becomes exhausted, you will notice his posture relaxing. This is an indication that he may require artificial ventilation very shortly. Alterations in mental status, combativeness, agitation, and confusion indicate a decreasing level of oxygen getting to the brain and an increasing level of carbon dioxide. A continuous decline would be an indication of the need for aggressive emergency care to include positive pressure ventilation with supplemental oxygen.

PATHOPHYSIOLOGY PEARLS

- Typically, inhalation is an active process requiring energy, whereas exhalation is a passive process requiring no energy.
- The patient with respiratory distress may have difficulty not only breathing in but also breathing out. He moves to active inhalation and active exhalation, both requiring energy. This may lead to faster muscle fatigue and early respiratory failure.
- Inspect the lips and around the nose and inside the mouth for cyanosis.
- Assess the neck for jugular vein distention, which might indicate an extreme increase in pressure in the chest or venous system. Inspect and palpate for an indrawing of the trachea and tracheal deviation. The trachea pulls inward during inhalation when constricted airflow is present. Tracheal deviation, which is a late sign, is the result of an extreme amount of pressure built up on one side of the chest, collapsing the lung and pushing the mediastinum (the tissues and organs between the lungs, including the heart) and the trachea to the opposite side. This is a sign of a life-threatening emergency.
Also inspect for retractions, or pulling of the tissue inward, involving the muscles of the neck, at the suprasternal notch, and behind the clavicles. This indicates that the patient is making an extreme effort to breathe and is another situation in which positive pressure ventilation with supplemental oxygen should be considered.

**ASSESSMENT TIPS**

When assessing the neck, look specifically for jugular vein distention during the inhalation phase of respiration. If the jugular veins distend during inhalation, and return to normal during exhalation, this is an indication of a severely increased pressure in the chest or around the heart. It is referred to as **Kussmaul sign**.

- **Inspect and palpate the chest** for retraction of the muscles between the ribs, asymmetrical chest wall movement, and also for subcutaneous emphysema, which is air trapped under the subcutaneous layer of the skin. It is felt as a crackling sensation, often described as "Rice Krispies" under the fingertips. Unequal chest wall movement may be a sign that air is trapped in one side of the chest cavity and preventing adequate ventilation. Subcutaneous emphysema is a common result of trauma to the neck and chest, indicating a hole in the lung, trachea, bronchus, or esophagus. Inspect for any evidence of trauma.

- **Auscultate the lungs** to determine whether the breath sounds are equal on both sides of the chest. Diminished or absent breath sounds on one side of the chest mean that the lung is not being adequately ventilated because of obstruction, collapse, or surrounding air or fluid. If both lungs have diminished or absent breath sounds, it is an indication that the breathing is inadequate and the patient needs immediate ventilation with supplemental oxygen connected to the ventilation device.

**PATHOPHYSIOLOGY PEARLS**

Subcutaneous emphysema is an indication that an air leak is present somewhere in an air-containing structure in the neck or chest. Gravity pulls heavier substances downward, forcing the air to travel upward toward the neck and head in the patient who is in a seated position.

Wheezing is a musical whistling sound that is heard in all lung fields upon auscultation of the chest. It is caused by narrowing of the lower airways, primarily the bronchioles, from bronchospasm and edema, or swelling. Wheezing is heard primarily during exhalation. You can expect to hear it most frequently in patients with a history of asthma or emphysema, but it may also be heard when fluid builds up in the lungs. These patients commonly carry medications that can be administered to reverse the bronchospasm and allow for greater air movement. Inspiratory crackles (rales) are indicative of fluid accumulation in the alveoli from a failing heart. This fluid decreases the gas exchange across the alveolar membrane and can lead to respiratory distress or failure. Finally, rhonchi are sounds heard in the larger airways and represent mucus accumulation.

**Vital Signs.** The systolic blood pressure may drop during inhalation. This is related to a drastic increase in pressure inside the chest. When taking the blood pressure by auscultation, watch the needle when obtaining the systolic pressure. If the needle suddenly drops more than 10 mmHg when the patient inhales, it is a significant finding of a severe respiratory condition such as obstructive lung disease. This finding is referred to as **pulsus paradoxus**. You may also note this as a sudden decrease in the amplitude (strength) of the pulse when the patient inhales. As the patient exhales, the pulse strength returns.

The heart rate may be increased (tachycardia) or decreased (bradycardia). Bradycardia in adults, infants, and children is a grave sign of extremely poor oxygenation, impending respiratory failure, and possible cardiac arrest. The skin is usually moist, pale, and cool (lung infections associated with breathing difficulty may produce warm, dry, or moist skin). The breathing rate is typically increased (tachypnea); however, it may decrease as the patient becomes tired and the oxygen levels drop significantly. Cyanosis may be noted in severely hypoxic patients.

Early application of a pulse oximeter, if available, is important in a patient with any evidence of respiratory distress, complaint of breathing difficulty, or signs of inadequate breathing. A pulse oximeter reading (SpO₂) of less than 94% in a patient with any breathing difficulty is a concern. This is an indication of hypoxemia (low oxygen levels in the blood). If the pulse oximeter reading is below 90%, this is a significant indication of severe hypoxemia.

Closely evaluate the ventilatory status (respiratory rate and tidal volume). If both are adequate, administer oxygen to maintain an SpO₂ of ≥94%. If either rate or tidal volume is inadequate, begin positive pressure ventilation. You would expect the pulse oximeter reading to increase once the patient is provided oxygen in adequate breathing or following positive pressure ventilation if the patient was breathing inadequately. Therefore, if a pulse oximeter reading can be obtained prior to any administration of oxygen or ventilation, it would provide a baseline reading for you to assess the effectiveness of your treatment.
If the SpO₂ reading continues to remain at 94% or less after the patient has been on supplemental oxygen for a period of time, it may indicate that the patient is still hypoxic and a disturbance in gas exchange is still present. If this patient were taken off the oxygen, you would expect the pulse oximeter reading to fall below a normal level, indicating severe hypoxemia. Normally, once oxygen has been applied or the patient is being ventilated, the SpO₂ should read >94% or higher. You may still experience a decline once the oxygen is removed. If the SpO₂ reading does not increase to >94% or higher after oxygen administration, be concerned that a hypoxemic state still exists.

At any time you suspect that the patient is not breathing adequately, you must immediately begin to ventilate using a bag-valve mask or other ventilation device with oxygen connected to the device. It is important to note that even though the patient is breathing, he may need to be ventilated. You would integrate your ventilation into the patient’s own spontaneous pattern and rate of breathing to produce an effective rate and tidal volume. Do not hesitate to ventilate a spontaneously breathing patient who has an inadequate rate or tidal volume. A poor SpO₂ reading may assist you in making the decision to ventilate. For example, if a patient were breathing at 38 times per minute with a shallow tidal volume and had an SpO₂ reading of 88%, you would immediately make the decision to ventilate the patient with a bag-valve-mask device. You would ventilate at 10–12 times per minute, adding your ventilation to the patient’s spontaneous breathing.

**Signs and Symptoms.** A wide variety of signs and symptoms may be associated with breathing difficulty, depending on the location of the obstruction or disease process, the mental state of the patient, and the severity of the respiratory distress. A large number of respiratory conditions, including both medical illness and traumatic injuries, cause signs and symptoms of breathing difficulty. Not all of the signs or symptoms will be present with each patient, nor will you find two cases that are exactly alike. The degree of difficulty in breathing can vary widely from minor to severe.

**Assessment Tips**

Respiratory distress may be produced by both medical illnesses and traumatic injuries. Do not assume that a patient in respiratory distress is suffering a medical illness, but expose the patient and inspect for any evidence of traumatic injuries, especially in the patient with a sudden onset of symptoms.

It is important to recognize that the degree of shortness of breath or the severity of the complaint of shortness of breath does not correlate with the level of hypoxia. In other words, a patient who states that his severity of dyspnea is a “10” on a scale of 1 to 10, with 10 being the worst, is not necessarily more hypoxic than the patient who complains of “a little shortness of breath” with a severity of “3” on the same scale. It is possible that the patient who perceives the level 3 severity is much more hypoxic than the one who perceives the level 10 severity. A pulse oximeter and a good physical exam would provide the evidence to determine the hypoxia levels of the two patients. Also, remember that hypoxic patients may experience an altered mental status in which they do not complain of the shortness of breath as readily as patients who are not as short of breath.

**Assessment Tips**

The severity of shortness of breath does not directly correlate with the level of hypoxia. A severely hypoxic patient may not complain of extreme shortness of breath. Pay close attention to your assessment findings.

The key is to recognize the patient who is having any difficulty in breathing, perform an accurate assessment, and manage any immediate life threats. The following are common signs of breathing difficulty:

- Shortness of breath (dyspnea)
- Restlessness, agitation, and anxiety
- Increased heart rate (tachycardia) or irregular heart rate in adults and children and a sudden decrease in heart rate (bradycardia) in newborns
- Faster-than-normal breathing rates (tachypnea)
- Slower-than-normal breathing rates (bradypnea)
- Cyanosis to the core of the body, usually seen in the face, neck, and upper chest (This is a late sign of hypoxia. Pale skin is seen earlier than cyanosis as a sign of hypoxia. Flushed, or red, skin may indicate an allergic reaction. With any of these discolorations, the skin is typically moist.)
- Abnormal upper airway sounds: crowing, gurgling, snoring, and stridor
- Audible wheezing upon inhalation and exhalation (In some conditions, wheezing on exhalation will develop before wheezing on inhalation. Auscultation with a stethoscope may reveal wheezing and crackles that cannot be heard by just listening with the ear.)
- Diminished ability or inability to speak
- Retractions from the use of accessory muscles in the upper chest and between the ribs and use of the muscles of the neck in breathing
- Excessive use of the diaphragm to breathe, producing abdominal breathing in which the abdomen is moving significantly during the breathing effort
- Shallow breathing, identified by very little chest rise and fall, and poor movement of air in and out of the mouth
- Coughing, especially if it is a productive cough that produces mucus
- Irregular breathing patterns
- Tripod position
- Barrel chest (Figure 16-16) indicating emphysema, a chronic respiratory condition
- Altered mental status—from disorientation to unresponsiveness
- Nasal flaring, when the nostrils widen and flare out upon inhalation
Tracheal indrawing
Paradoxical motion, in which an area of the chest moves inward during inhalation and outward during exhalation—a sign of significant chest trauma; can lead to ineffective ventilation
Indications of chest trauma (e.g., open wounds)
Pursed-lip breathing, where the lips are puckered during exhalation

Emergency Medical Care

Do not take the time to try to determine the exact cause of the breathing difficulty unless it is in the trauma patient with a possible chest injury that must be managed in addition to the breathing difficulty itself. A trauma patient complaining of difficulty in breathing requires exposure of the chest and back with close inspection for and management of life-threatening injuries. Chest injuries will be discussed in more detail in Chapter 34, “Chest Trauma.”

Aside from the management of any chest injuries, you will use the same strategies for managing breathing difficulty and respiratory distress no matter what its cause or underlying disease process.

A patient with breathing difficulty and respiratory distress may deteriorate rapidly. Continuously assess the airway for possible obstruction and the ventilation status for inadequacy. Have your ventilation equipment ready and be prepared to control the airway and begin positive pressure ventilation with supplemental oxygen if the patient deteriorates to respiratory failure. Delays in providing adequate ventilation can adversely affect the outcome of the patient in a short period of time. If you are ever in doubt about whether to ventilate, it is better to provide the positive pressure ventilation with supplemental oxygen. Waiting may cost the patient his life.

The following are guidelines for emergency care of the patient with respiratory distress or failure:

**Inadequate Breathing (Respiratory Failure).** If signs of inadequate breathing (respiratory failure) are present—poor chest rise and fall, poor volume heard and felt, diminished or absent breath sounds, inadequate rate (too fast or too slow), or severely altered mental status:

1. *Establish an open airway.* Insert an oropharyngeal or nasopharyngeal airway if possible to maintain the airway. If the patient is still responsive, do not insert an airway. Be sure to explain to the patient that you are going to ventilate him to assist and improve his breathing.
2. *Begin positive pressure ventilation with supplemental oxygen.* Check for signs of adequate ventilation (see the next section).
3. *Expeditiously transport* the patient to the hospital.

**Adequate Breathing (Respiratory Distress).** If the breathing is adequate (adequate chest rise and fall, good volume of air being breathed in and out, good breath sounds bilaterally, and adequate rate) but the patient complains of difficulty in breathing (respiratory distress):

1. *Continue administration of supplemental oxygen.*
2. *Assess the baseline vital signs.*
3. *Determine if the patient has a prescribed* beta, metered-dose inhaler (MDI). If so, contact medical direction for permission to administer the medication. Assist the patient with administration of the medication. Be sure to comply with local protocols.
4. *Place the patient in a position of comfort,* most typically in a Fowler’s or semi-Fowler’s (sitting-up) position, and begin transport.
5. *Complete the secondary assessment.* If your protocol allows, the patient’s condition is appropriate, and the indications are present, in cases of severe respiratory distress consider the use of continuous positive airway pressure (CPAP). Current studies show that patients in severe respiratory distress from a variety of conditions may benefit from CPAP. (See Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”)

Reassessment

En route to the hospital, perform a reassessment to determine if your emergency care has improved the respiratory distress or respiratory failure or if further intervention is necessary. Better ventilation and oxygenation should improve the patient’s mental status. Closely
monitor the patient’s airway for possible occlusion and the ventilation status for signs of inadequate breathing. If the patient continues to deteriorate, it may be necessary to begin positive pressure ventilation with supplemental oxygen. Monitor the SpO2 reading. An increase in the SpO2 indicates improvement in the condition, whereas a decrease may indicate a worsening condition with further hypoxia. Always assess the respiratory rate and tidal volume when there is a decrease in the SpO2 reading.

Monitor the pulse for changes in the heart rate and regularity. A decreasing heart rate in a patient who has tachycardia may indicate improvement if the mental status is also improving and the respiratory distress is subsiding. If the heart rate is declining along with the mental status, and the respiratory distress is worsening, this is an ominous sign of impending respiratory failure. Increases in the heart rate may be seen with the administration of many of the metered-dose inhalers. These medications mimic the actions of the sympathetic nervous system; therefore, a slight increase in heart rate may be anticipated. This tachycardia would be expected to decrease once the condition improves and the medication begins to wear off.

**PATHOPHYSIOLOGY PEARLS**

Beta2 metered-dose inhalers also contain trace beta1 properties. Beta1 properties increase the heart rate and the force of contraction. An increase in the heart rate following the administration of a beta2 MDI is often a side effect from the trace beta1 properties.

**Assessment Summary**

**RESPIRATORY DISTRESS**

The following are findings that may be associated with breathing difficulty.

**Scene Size-up**

Is breathing difficulty due to a medical or a traumatic cause? Look for evidence of:
- Mechanism of injury—collision, fall, guns, knives, bruising on chest
- Home or portable oxygen tanks or concentrators indicating chronic respiratory problems
- Alcohol or food that may indicate choking

**Primary Assessment**

**General Impression**

Position of patient:
- Tripod
- Lying flat

Moist skin (diaphoresis) is a result of the sympathetic nervous system response in the patient with breathing difficulty. An increase in diaphoresis would correlate with a worsening condition.

Reassess and record the blood pressure. Reassess the breath sounds. Improved air movement in the lungs will produce clearer and louder breath sounds on both sides of the chest. Conversely, as the condition deteriorates, the breath sounds become diminished to absent. Note that decreased wheezing may not indicate improvement; it may actually indicate severe bronchoconstriction with less air movement.

The patient with breathing difficulty is considered a priority patient, especially if the condition does not respond to your emergency care. You should consider advanced life support backup.

If the patient’s complaint changes, repeat the physical exam and vital signs. Ensure that the oxygen is applied properly and flowing adequately. Continuously assess the status of the breathing.

If positive pressure ventilation with supplemental oxygen has been initiated, continuously assess its effectiveness. Ensure that oxygen is connected and adequately flowing to the pocket mask or the reservoir of the bag-valve-mask device.

**Summary: Assessment and Care**

To review assessment findings that may be associated with breathing difficulty and emergency care for breathing difficulty, see Figures 16-17 and 16-18.

Facial expression:
- Agitated or confused

Speech:
- Patient may gasp for breath between words.

Mental Status
- Alert to unresponsive
- Restlessness
- Agitation
- Disorientation

Airway
- Inspect for incomplete or partial obstruction
- Crowing and stridor (indicate partial obstruction)
- Gurgling (indicates fluid in the airway; suction required)

Breathing
- Signs of inadequate breathing, including poor chest rise and fall, poor volume heard and felt, diminished or absent breath sounds
- Wheezing heard on auscultation
**Emergency Care Protocol**

**RESPIRATORY DISTRESS**

1. Establish and maintain an open airway.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. Apply a pulse oximeter. If breathing is adequate, administer oxygen to maintain an SpO2 of ≥94%.
5. If the patient has signs and symptoms of breathing difficulty and has a prescribed metered-dose inhaler or a nebulization device, administer the beta 2-specific drug as appropriate according to medical direction:
   - Beta 2-specific drugs mimic the sympathetic nervous system and cause bronchodilation.
   - Dose is precisely delivered by the device.
   - Obtain an order from medical direction.
   - Ensure the “five rights” of medication administration.
   - Assemble the equipment (MDI or nebulizer) as discussed previously.

   - Nasal flaring
   - Pursed-lip breathing
   - Cough
   - Retractions
   - Accessory muscle use
   - Wheezing
   - Productive cough
   - Barrel chest (indicates emphysema, a chronic respiratory condition)

6. Consider advanced life support if the condition does not improve.
8. Perform a reassessment of the patient’s status every 5 minutes.
9. Complete the secondary assessment. If your protocol allows, in cases of severe respiratory distress consider the use of continuous positive airway pressure (CPAP). Current studies show that patients in severe respiratory distress from a variety of conditions may benefit from CPAP. (See Chapter 10, “Airway Management, Artificial Ventilation, and Oxygenation.”)

**Baseline Vital Signs**

- BP: normal
- BP: sudden decrease in the systolic BP by 10 mmHg or greater with inhalation
- HR: increased in adults; slow in infants and young children
- Pulse: sudden decrease in the pulse amplitude with inhalation
- RR: increased; may decrease with greater hypoxia
- Skin: cyanosis, paleness, diaphoresis
- Pupils: dilated; sluggish to respond to light
- SpO2: 94%

---

**History and Secondary Assessment**

**History**

Signs and symptoms:
- Shortness of breath
- Restlessness and anxiety
- Difficulty in breathing while lying flat
- Diaphoresis

Known allergies to medication or other substances

Medications for respiratory conditions

Home oxygen
- Prescribed metered-dose inhaler (MDI)
- Pre-existing respiratory or cardiac disease
- Hospitalized for respiratory condition

**Physical Exam**

Head, neck, and face:
- Cyanosis to face, neck, and mucous membranes
- Jugular venous distention (may indicate heart failure or lung injury [tension pneumothorax])
- Jugular vein engorgement on inhalation (Kussmaul sign)
- Cyanosis to fingers and nail beds
- Pale skin
- Diaphoresis

**Circulation**

- Tachycardia (more typical in adult with hypoxia)
- Bradycardia (more typical in infant or young child with hypoxia)
- Cyanosis to mucous membranes, around nose and mouth, nail beds, chest, and neck

Status: Priority Patient

**FIGURE 16-17A** Assessment summary: respiratory distress.

**FIGURE 16-17B** Emergency care protocol: respiratory distress.
Emergency Care Algorithm

RESPIRATORY DISTRESS/FAILURE/ARREST

- Mechanism of injury present?
  - Yes
    - Consider manual in-line stabilization and assess for spinal injury later in the assessment
    - Open wound to chest?
      - Yes
        - Occlude with nonporous dressing
      - No
    - Obvious flail segment?
      - Yes
        - Consider, CPAP or PPV
      - No
        - Assess mental status
  - No
    - Alert and able to obey commands
    - Administer oxygen
    - Assess circulation
    - Secondary assessment
      - Prescribed metered dose inhaler (MDI)?
        - Yes
          - Administer MDI
        - No
          - Administer oxygen
          - Assess circulation
          - Rapid secondary assessment
          - Transport
          - Reassessment

- Airway open?
  - Yes
    - Suction if necessary
    - Head-tilt, chin-lift or jaw thrust
    - Oro- or nasopharyngeal airway
    - Assess breathing
    - Adequate
    - Inadequate
    - Administer oxygen
    - PPV with O₂
    - Assess circulation
    - Rapid secondary assessment

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

- Figure 16-18  Emergency care algorithm: respiratory distress/failure/arrest.
EMT SKILLS 16-1 Auscultating the Chest

- **16-1A** Auscultate the anterior chest at the second intercostal space at each midclavicular line.
- **16-1B** Auscultate the lateral chest at the fourth to fifth intercostal space at each midaxillary line.
- **16-1C** Auscultate the posterior chest below the tip of the scapula on each midscapular line.
Administering Medication by Metered-Dose Inhaler

**16-2A** Consult with medical direction for an order to administer the medication.

**16-2B** Check to make sure the medication is for the patient, that it is the proper one to administer, and that it has not reached its expiration date.

**16-2C** Shake the inhaler vigorously for at least 30 seconds.

**16-2D** Instruct the patient to inhale slowly and deeply for about 5 seconds. As the patient begins to inhale, depress the canister.

**16-2E** Remove the inhaler and instruct the patient to hold the breath for 10 seconds or for as long as is comfortable.

**16-2F** Instruct the patient to exhale slowly through pursed lips.
Replace the oxygen on the patient. Reassess the breathing status and vital signs.

**EMT SKILLS 16-3**

**Administering a Metered-Dose Inhaler with a Spacer**

- 16-3A Remove the spacer cap. Attach the spacer to the inhaler mouthpiece.
- 16-3B Depress the medication canister to fill the spacer with medication.
- 16-3C Instruct the patient to inhale slowly and deeply. The spacer may whistle if the patient is inhaling too quickly.
EMT SKILLS 16-4

Administering Nebulized Medications

16-4A Complete the primary assessment and assess the patient’s pulse rate and breath sounds.

16-4B Select the correct medication and consult with medical direction for an order to administer the medication.

16-4C Add the medication to the nebulizer chamber.

16-4D Assemble the nebulizer.

16-4E Coach the patient to inhale the nebulized medication from the mouthpiece.

16-4F Reassess the patient’s pulse rate and breath sounds.

continued
Respiratory emergencies can range from a patient experiencing respiratory distress to a patient who is in respiratory arrest. It is imperative to effectively assess the patient to determine if the condition is respiratory distress, respiratory failure, or respiratory arrest. The patient with breathing difficulty who is in respiratory distress is still able to compensate for the disturbance and needs supplemental oxygen to improve his oxygenation status. The patient in respiratory failure, as the name implies, has failed to continue to meet the metabolic demands of the body, and the respiratory rate or tidal volume is no longer adequate. This patient needs immediate ventilation with a bag-valve mask or other ventilation device and supplemental oxygen. A patient in respiratory arrest is no longer breathing and also needs immediate positive pressure ventilation.

A patient in respiratory distress who has a history of asthma, emphysema, or chronic bronchitis may have a metered-dose inhaler or home nebulizer unit that delivers a beta₂-specific drug. If so, you may assist the patient in using the device to relieve the bronchoconstriction that is impeding airflow into the alveoli.

Infants, children, and geriatric patients may present differently than adults when experiencing a respiratory emergency. Quick intervention is necessary since the most common cause of cardiac arrest in pediatric patients is from an airway or respiratory compromise, and geriatric patients may rapidly deteriorate because of poor compensatory mechanisms.
Case Study Follow-up

Scene Size-up
You have been dispatched to a 31-year-old female patient complaining of difficulty in breathing. A man nervously greets you at the curb as you gather your equipment. He indicates that the patient is his wife, Anna Sanders, who is having an extremely hard time breathing. You are led up to the third floor of an apartment complex. You do not note any possible hazards, but are looking at how difficult the extrication might be. Upon walking into the apartment you note a young female patient sitting in a tripod position next to the kitchen table.

Primary Assessment
As you start to introduce yourself, the patient begins to speak, gasping for her breath after each word. With great difficulty she states, “I—can’t—breathe.” Based on Mrs. Sanders’s facial expression and posture, she appears to be in a great deal of distress. Her airway is open and her breathing is rapid and labored at a rate of 34 per minute. There are audible wheezes when she exhales. The SpO₂ is 78% on room air; thus, you decide to immediately apply oxygen via a nonrebreather mask at 15 lpm to maximize oxygenation of the patient. Her radial pulse is about 110 per minute. The skin is moist and slightly pale. You recognize the patient as a priority and signal your partner to get the stretcher while you continue with the secondary assessment.

Secondary Assessment
You begin to evaluate the difficulty in breathing using the OPQRST mnemonic. You ask Anna questions she can answer with a nod or a shake of her head to reduce her need to respond by speaking. Some questions you direct to her husband. You ascertain that the breathing difficulty began gradually about 2 hours ago and got progressively worse. She is unable to lie down because this causes her breathing to get much worse, although sitting up is not much better. She has had similar episodes in the past, but none seem to have been this severe. On a scale of 1 to 10, Mrs. Sanders indicates that her difficulty in breathing is about an 8 or 9.

You continue to obtain a history. The primary symptom is severe difficulty in breathing. Mrs. Sanders has an allergy to penicillin. When asked about medications that she takes, Mr. Sanders brings you a prescription of albuterol in a metered-dose inhaler. She is on no other medication. When asked if she has taken any of the albuterol, her husband says, “She took one puff about 15 minutes ago.” She has a past medical history of asthma and suffers these attacks maybe once every four or five months. She has had nothing to eat for about 3 hours but drank a small glass of orange juice about an hour ago. She was cleaning the kitchen when the episode began.

You quickly perform a physical exam. You assess her neck for jugular vein distention. Inspection of her chest and abdomen reveals significant use of the abdominal muscles when exhaling. The breath sounds are diminished bilaterally and you hear wheezing even without using your stethoscope. Her fingertips are slightly cyanotic. You assess the baseline vital signs and find a blood pressure of 134/86; pulse of 118 per minute and regular; respirations at 32 per minute and labored with audible wheezing; the skin moist and slightly pale. Her SpO₂ reading is 78% prior to oxygen administration.

The patient meets the criteria for CPAP administration and does not present with any contraindications. You explain the procedure and equipment to the patient and initiate and increase the pressure to 5 cmH₂O. You contact your medical director, Dr. Maxwell, for an order to administer the albuterol by a small-volume nebulizer in conjunction with the CPAP device. You check the medication to ensure it is prescribed to Mrs. Sanders, that it is the correct medication, and that it has not expired. You report your physical findings and history to Dr. Maxwell. He gives you an order to administer one dose. If there is no relief of the symptoms, he instructs you to contact him for further orders. You proceed with administration of albuterol with the CPAP.

Reassessment
You reassess the vital signs following administration of the albuterol. The blood pressure is 130/84, pulse rate decreases to 90 per minute, and respirations are now 18 per minute and much less labored. Her SpO₂ reading is 96%. The audible wheezes are minimal. The skin is not as moist and both skin and fingernails begin to return to a normal color. You secure Mrs. Sanders in a Fowler’s position on a chair, and you and your partner transport her down to a stretcher your partner has placed on the first floor.

You reassess the difficulty in breathing. Mrs. Sanders is now able to talk in complete sentences and indicates that the shortness of breath is much less severe. She is now only slightly short of breath. As a result of the excellent response of the patient to the treatment, you switch the oxygen therapy to a nasal cannula at 2 lpm, document your findings and emergency care, and radio the hospital with a report.

Upon arrival at the hospital, you provide the nursing staff with an oral report. You write a prehospital care report form as your partner restocks the ambulance. Before leaving the hospital, you check in on Mrs. Sanders and find her to be relaxed and breathing well. She thanks you for your prompt response and emergency care. You then mark back in service and prepare for the next call.

An author podcast is available by going to www.bradybooks.com, Author Podcasts.
IN REVIEW

1. List the major signs and symptoms of breathing difficulty.
2. List the signs of adequate breathing.
3. List the signs of inadequate breathing.
4. List the steps of emergency care for a patient who is exhibiting signs and symptoms of breathing difficulty but is breathing adequately (respiratory distress).
5. List the steps of emergency care for a patient who is in respiratory failure.
6. List the signs of adequate positive pressure ventilation and the steps to take if ventilation is inadequate.

7. Explain the steps to administer a medication by metered-dose inhaler and by small-volume nebulizer.
8. List the indications and contraindications for the use of a beta-agonist drug.
9. Describe the early signs of breathing difficulty in the infant or child; list the signs of inadequate breathing and respiratory failure in the infant or child.
10. Explain how to distinguish airway obstruction in the infant or child patient caused by disease, from airway obstruction caused by a foreign body; explain how treatment would differ for the two types of airway obstruction.

CRITICAL THINKING

You arrive on the scene and find a 72-year-old female patient sitting up in her recliner in the living room of her home. She looks very fatigued and appears to be in severe respiratory distress. As you approach her, she appears extremely pale and diaphoretic with circumoral cyanosis. Her head is bobbing with each breath. As you ask her name, she can barely say it. She is gasping with each breath she takes. Her respiratory rate is 36 per minute with a shallow tidal volume. Her radial pulse is weak and rapid. Her skin is pale, very cool, and extremely moist. Her nail beds and fingertips are cyanotic. Her SpO₂ reading is 82%. Her blood pressure is 92/70 mmHg. She has a history of congestive heart failure, two previous heart attacks, and hypertension.

1. What would be the immediate emergency care provided during the primary assessment?
2. What is the respiratory status of the patient?
3. How would you manage the respiratory status of the patient?
4. What would you expect to find upon auscultation of the lungs?
5. What areas of the lungs would be most important to auscultate?
6. What would be the most effective method to increase oxygenation in the patient?
Cardiovascular Emergencies

The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • *Medicine* (Content Area: Cardiovascular)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

17-1. Define key terms introduced in this chapter.
17-2. Describe the relationship between chest pain or discomfort, heart disease, and cardiac arrest.
17-3. Describe the structure and function of the circulatory system, including:
   a. The cardiac conduction system
   b. Conductive tissue and conductivity
   c. Contractile tissue and contractility
   d. Automaticity
   e. Effects of the autonomic nervous system (sympathetic and parasympathetic) on the heart
   f. Gross anatomy of the heart
   g. Systemic and pulmonary circulation
   h. Coronary arteries
   i. Plasma and formed elements of the blood
17-4. Explain the relationship between electrical and mechanical events in the heart.
17-5. Describe the processes of depolarization and repolarization, and relate the waves and intervals of a normal electrocardiogram (ECG) to the physiological events they represent.
17-6. Discuss the relationship between hypoxia, damage to the cardiac conduction system, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation.
17-7. Describe the roles of the heart and blood vessels in maintaining normal blood pressure.
17-8. Explain the importance of early recognition of signs and symptoms and the early treatment of patients with cardiac emergencies.
17-9. Explain the pathophysiology and the appropriate assessment and management of the following conditions that may be classified as cardiac compromise or acute coronary syndrome:
   a. Angina pectoris
   b. Myocardial infarction
   c. Aortic aneurysm or dissection
   d. Congestive heart failure
   e. Cardiogenic shock
   f. Hypertensive emergencies
   g. Cardiac arrest
17-10. Explain the typical presentation of myocardial ischemia or infarction in females.
17-11. Explain the indications, contraindications, forms, dosage, administration, actions, side effects, and reassessment for nitroglycerin.
17-12. Explain the special considerations in assessing and managing pediatric and geriatric patients with cardiac emergencies.
17-13. Explain the assessment-based approach to assessment and emergency medical care for cardiac compromise and acute coronary syndrome.
17-14. Discuss the indications and contraindications for percutaneous intervention (angioplasty) or fibrinolytic therapy in patients with cardiac emergencies.
17-15. Given a series of scenarios, demonstrate the assessment-based management of a variety of patients with cardiovascular emergencies, including: Explain the indications, contraindications, forms, dosage, administration, actions, side effects, and reassessment for aspirin.
INTRODUCTION

Some—though certainly not all—patients with chest discomfort or pain are experiencing a heart attack, and some may deteriorate into cardiac arrest at the scene or en route to the hospital. Because of the potential for a severe and often fatal event, the EMT must treat every patient with signs and symptoms of cardiac compromise as a cardiac emergency.

Heart disease is America’s number one killer. While the EMT will occasionally be called to a patient who is in cardiac arrest or who goes into cardiac arrest before reaching the hospital, more often the call will be to a responsive patient who has signs and symptoms—particularly chest discomfort or pain—that may be caused by heart disease. Although not every cardiac arrest is preceded by chest discomfort or pain, nor do all patients with chest discomfort or pain proceed to cardiac arrest, for those who do, rapid intervention is vital. 

REVIEW OF THE CIRCULATORY SYSTEM ANATOMY AND PHYSIOLOGY

The following is a brief review of the anatomy and physiology of the circulatory system as it pertains more specifically to cardiac emergencies. For a more detailed discussion, review Chapter 7, “Anatomy, Physiology, and Medical Terminology.”

The Circulatory System

The circulatory system, also known as the cardiovascular system, has three major components: the heart, the blood vessels, and the blood. Each of these components may play a significant role in patients experiencing a cardiac-related emergency.

The Conduction System

The heart is more than just a muscle. It contains specialized conductive tissue (the cardiac conduction system, Figure 17-1 ■), which generates electrical impulses that are conducted rapidly to other cells of the heart (a property known as conductivity). The heart also contains specialized contractile tissue that allows the heart muscle to contract when stimulated by the electrical impulses from the conduction system.

Conductive cells are grouped in three areas of the heart—pacemaker sites—where the electrical impulses are created automatically, independent of the autonomic nervous system of the body (a property known as automaticity). One pacemaker site is the sinoatrial (SA) node, located in the upper portion of the right atrium. The SA node, known as the primary pacemaker of the heart, generates the impulse that triggers the rest

Case Study

The Dispatch

EMS Unit 23—respond to 321 Congress St., Reali’s Restaurant. You have a 49-year-old male complaining of chest discomfort. Time out is 1735 hours.

Upon Arrival

You and your partner arrive at 1740 hours and find the patient sitting in a chair at a table clutching his chest. As you approach the patient, you note that he looks very anxious. The scene is secure and he is the only patient. You introduce your partner and yourself. Your patient gives his name as Paul Antak. He states, “I feel like someone is standing on my chest.”

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from cardiovascular emergencies such as chest discomfort or pain and cardiac arrest. Later, we will return to the case and apply the procedures learned.
of the heart to contract. A secondary pacemaker site is located at the crux, the point where the walls that separate the upper and lower chambers and the left and right sides of the heart all cross. This pacemaker site, the atrioventricular (AV) node, only creates an impulse if the sinoatrial node fails. The final pacemaker site is widely distributed in the conduction system of the ventricles and is known as the Purkinje fibers or network. These fibers deliver the impulse to the working cells of the heart. If both higher pacemaker sites fail, the Purkinje network can also initiate an impulse to maintain some ventricular contraction.

The heart’s electrical impulses travel through the heart from the pacemaker sites via a conduction pathway that is composed of cells that neither initiate an impulse nor contract. Instead, the cells of the conduction pathway rapidly conduct each impulse to the rest of the heart muscle. They do this in a unified fashion so that, rather than the whole heart contracting at once, there is a sequential contraction of the chambers.

In addition to the conductive cells of the heart, there is another group of cells that are often called the “working” cells of the heart, also called contractile cells. Their primary purpose is to contract in response to the electrical impulses provided by the conduction system. These working cells have characteristics of both smooth (involuntary) muscle and skeletal (voluntary) muscle. Like skeletal muscle, they contract strongly when stimulated to help eject blood from the heart. Like smooth muscle, they contract completely, to a very small size, because the heart has to collapse upon itself in order to push blood out of the chambers.

The conduction cells and working cells operate together in unison to fulfill the heart’s sole purpose: pumping blood.

The heart’s activity is monitored by the body to ensure that it is meeting the body’s blood flow requirements. If the heart’s activity needs to be modified, assistance is provided by the autonomic nervous system. (Although the heart initiates electrical impulses on its own, the overall heart rate and force of contraction can be influenced by the autonomic nervous system.)

The sympathetic branch of the autonomic nervous system innervates all three pacemaker sites and the working cells of the heart. When the body needs increased blood flow, the sympathetic nervous system is stimulated and causes the heart to beat faster and with greater contractile force, which increases the ejection of blood. The parasympathetic branch of the autonomic nervous system innervates the sinoatrial and atrioventricular nodes. When the parasympathetic nervous system is stimulated, it slows the heart rate and eases the force of contraction. This diminishes cardiac output in situations where strong output is not needed, for example while the body is sleeping or at rest.

**The Heart**

The heart (Figure 17-2) consists of four chambers: the atria (the two top chambers) and the ventricles (the two bottom chambers). As mentioned, the heart has only one purpose: pumping blood within the body. If that single purpose is interrupted, even momentarily, cardiac arrest ensues and the chance of survival is slim.

The right atrium receives deoxygenated blood from the inferior and superior vena cavae, the largest veins within the body. Upon contraction, the blood in the right atrium travels through the tricuspid valve and into the right ventricle. From the right ventricle, with the next contraction, the deoxygenated blood is ejected through the pulmonic semilunar valve and into the pulmonary arteries. The pressure in the pulmonary vessels is very low; thus the right ventricle does not have to generate a great deal of force to eject the blood. In some pulmonary (lung) diseases, such as emphysema, however, the pulmonary vessels are compressed or narrowed. This increases the pressure in the pulmonary vessels and makes it much more difficult for the right ventricle to pump the blood out. If this high pressure is sustained over time, the right ventricle begins to weaken and eventually may fail. This is referred to as right-sided or right ventricular heart failure, also known as cor pulmonale.
After the blood is oxygenated in the alveoli of the lungs, it returns to the left atrium via the pulmonary veins. The blood in the left atrium is then ejected through the mitral valve (also called the bicuspid valve) and into the left ventricle upon contraction of the atria. On the next ventricular contraction, the blood is ejected through the aortic semilunar valve and into the aorta. The blood is then distributed throughout the body to cells and organs (Figure 17-3). The pressure in the aorta is very high; therefore, the left ventricle must generate a significant amount of force to eject the blood against this pressure. If the pressure in the aorta is excessively high, as seen in severe hypertensive patients (those with very high blood pressure), or if the blood pressure is simply higher than normal over a long period of time, the left ventricle will begin to weaken and fail. Also, if the left ventricle muscle is damaged due to a blockage of a coronary artery, the ventricle will weaken and will not be able to pump an adequate amount of blood out of the left ventricle. This may lead to congestive heart failure, also known as left-sided or left ventricular failure.

**PATHOPHYSIOLOGY PEARLS**

Left-sided heart failure may result from a constantly high resistance in the arteries causing the ventricle to pump harder or from death to a portion of the left ventricular wall from a coronary artery occlusion. Either circumstance can cause the left ventricle to weaken and eventually fail.

When the left ventricle cannot eject the blood effectively, pressure in the left atrium and pulmonary veins begins to build up. This may force fluid out of the capillaries around the alveoli of the lungs, causing a severe gas exchange problem, leading to hypoxia and severe shortness of breath. This condition is known as pulmonary edema. It is important to note that older adults are not the only ones to suffer from heart failure. An 18-year-old who has been using cocaine may suffer heart failure from severe vessel constriction that drastically increases the blood pressure and causes the heart to fail. Also, a young person may suffer a heart attack that destroys a portion of the heart muscle, leading to...
heart failure, cardiac rhythm disturbances, or sudden cardiac death.

The Vessels

The arteries carry oxygenated blood to the arterioles and then to the capillaries, which interface with cells throughout the body. Capillary walls are so thin that oxygen and nutrients carried in the blood are able to move out of the capillaries and into the body’s cells. (The exception to the rule that arteries carry oxygenated blood is the pulmonary arteries, which carry deoxygenated blood from the right ventricle to the lungs to be oxygenated. All arteries, however, carry blood away from the heart.) The veins carry deoxygenated blood from the capillaries, where the blood has picked up carbon dioxide and other waste products given off by the cells, through the venules, to the veins and back to the right ventricle through the inferior and superior vena cava. (Again, the exception to the rule that veins carry deoxygenated blood is the pulmonary veins, which carry oxygenated blood from the lungs back to the left atrium. However, all veins carry blood toward the heart.)

There are many arteries and veins (Figure 17-4a and 17-4b) as well as smaller arterioles, capillaries, and venules that circulate blood throughout the body.

Coronary Arteries. The heart perfuses itself, first, with oxygenated blood before sending the oxygenated blood on to the arteries throughout the body. The coronary arteries (Figure 17-5) are the first two arteries to originate off the aorta and are the same arteries that are associated with many cardiac emergencies. These two arteries branch off from the base of the aorta and are responsible for supplying the heart with a rich supply of oxygenated blood. (The heart gets its blood supply from the coronary arteries, not from the blood that is pumped through its chambers.)

The heart is a muscle that requires a constant supply of oxygenated blood to continue pumping effectively. A good analogy to this concept would be to place a tourniquet around a person’s upper arm and ask him to lift a 10-pound weight continuously. How long will he be able to lift the weight before his muscle begins to fatigue without an adequate supply of oxygenated blood? He will not be able to lift the weight for very long at all. Once the tourniquet is removed, the muscle will begin
**FIGURE 17-4a** Major arteries.
**FIGURE 17-4b** Major veins.
to function adequately again. The concept is the same with the coronary arteries. If a large coronary artery is blocked, it is unable to supply an adequate amount of blood to the heart muscle. Eventually, if the occluded coronary artery is not opened or unblocked, the heart muscle will become hypoxic and begin to die. During the ensuing ischemic process, the muscle may weaken and lead to a heart attack or heart failure, or the muscle may become irritable and cause abnormal electrical cardiac rhythms, some of which may be lethal.

**The Blood**

The blood is composed of several components that serve multiple functions for the body. The liquid portion of the blood, the serum, serves as the transport medium for the formed elements. The formed elements include the red blood cells which, among other functions, carry oxygen to the tissues of the body. There are also white blood cells that serve to protect the body and eliminate infections from viruses or bacteria. Platelets are cellular elements whose job is to help in the clotting process to stop bleeding.

These functions of the blood also play a major role in cardiac emergencies. The most significant function in a cardiac emergency is the coagulation process. Blood components respond to injury by forming clots in order to stop the bleeding. The clot that is formed is called a thrombus. Several components are involved in the clot formation system, the most important of which are platelets (disk-shaped elements in the blood that are fragments of cells from the bone marrow), thrombin (a protein responsible for activating the formation of a clot), and fibrin (strands that are responsible for making the clot stronger).

A thrombus may form within a coronary artery at a site where plaque (a fatty deposit) has built up. The thrombus (clot) formation develops in the following way: A plaque deposit inside the coronary artery may weaken over time and rupture. The body views the plaque rupture as an injury and sends out a cascade of substances to form a clot to stop the bleeding at the injury site. Platelets begin to cover the site and thrombin is activated to form a clot. The clot may partially or completely occlude the coronary artery, cutting off or reducing the supply of oxygenated blood to the heart muscle (Figure 17-6). The heart muscle becomes deprived of oxygen and may eventually begin to die. This may lead to a heart attack, pump failure, or serious cardiac rhythm disturbances.

**Cardiac Contraction**

The heart's electrical impulse is first generated in the right atrium at the SA node. It travels through both right and left atria by way of the Bachmann bundle. Both atria contract simultaneously as a result of the electrical impulse (a process known as atrial systole), ejecting the blood into the ventricles through the atrioventricular valves that open when the pressure in the atria exceeds the pressure in the ventricles. The impulse then travels to the AV node by way of an intranodal tract, located in the area between the atria and the ventricles. There the impulse is inhibited very briefly to allow the blood from the contracted atria to fill the ventricles, and then the impulse travels down the bundle of His to the left and right ventricles via the left and right bundle branches.
From the bundle of His and the left and right bundle branches, the electrical impulse travels to the Purkinje fibers, which are embedded in the ventricular muscle, causing the ventricles to contract simultaneously (a process known as ventricular systole). As pressure rapidly increases in the ventricles, it first causes the atrioventricular valves to close. When the pressure exceeds that exerted on the semilunar valves, they open and blood from the right ventricle is propelled toward the lungs while blood from the left ventricle is propelled throughout the body via the aorta.

If the heart rate and force of contraction need to increase or decrease based on the body’s demand, the autonomic nervous system facilitates this modification via the sympathetic and parasympathetic nervous systems, as described previously. After the systolic phases of the atria and/or ventricles, there is a diastolic phase in which the heart cells repolarize and await the next impulse, as described in the next section.

When the coronary arteries are occluded, either partially or completely, the conduction system may become irritable from the lack of oxygen. When this occurs, the conduction cells may begin to “fire off” impulses on their own. This may lead to cardiac rhythm abnormalities called dysrhythmias. Some of these dysrhythmias may lead to sudden death.

The Electrocardiogram

The electrocardiogram (ECG or EKG) is a graphic representation of the heart’s electrical activity as detected from the chest wall surface. The ECG may be displayed on a monitor screen or on a continuous strip of special graph paper that can record changes in heart activity over a period of time.

Each heartbeat, or mechanical contraction of the heart, has two distinct components of electrical activity: depolarization and repolarization. Depolarization is the first, in which electrical charges of the heart muscle change from positive to negative and cause heart muscle contraction. Repolarization is the second component, in which the electrical charges of the heart muscle return to a positive charge and cause relaxation of the heart muscle.

The human body acts as a conductor of electrical current. Any two points on the body may be connected with electrodes or electrical “leads” to record the heart’s electrical activity. The recording or tracing of this electrical activity produces a graphic representation of depolarization and repolarization in the form of complexes or a series of waves normally occurring at regular intervals. The waves, or deflections, of a normal ECG have three portions (Figure 17-7):  

- **P wave.** This is the first waveform of the ECG and represents the depolarization (contraction) of the atria.
- **QRS complex.** This is the second waveform and represents the depolarization (contraction) of the ventricles and the main contraction of the heart.
- **T wave.** This is the third waveform and represents the repolarization (relaxation) of the ventricles.

The atria also have a repolarization wave, but it is usually hidden within the QRS complex.

Another portion of the ECG, the PR interval (also referred to as the PRI), is measured in terms of time and used for analysis of the ECG. The PRI is calculated from the beginning of the P wave to the beginning of the QRS complex. It represents the time it takes the heart’s electrical impulse to travel from the atria to the ventricles.

In a normally functioning heart, as described earlier, the heart’s electrical impulse is generated from the sinoatrial node (review Figure 17-1). The electrical impulse then travels through the heart’s conduction system, depolarizing the muscle and producing the contraction that pumps blood into the ventricles and then through the body. This electrical activity is called normal sinus rhythm. It will produce an ECG pattern of regularly spaced peaks that occur between 60 and 100 times each minute, separated by nearly flat lines, as shown in Figure 17-7.

In some cases, the heart muscle becomes hypoxic, is injured, or dies. Also, the electrical conduction system may be damaged or disturbed and may cause the improper functioning of the heart. Sometimes these conditions produce an irritability of the heart that causes the uncoordinated firing of electrical ventricular impulses called premature ventricular complexes (PVCs). When PVCs occur in succession, they may produce ventricular tachycardia (V-Tach), which shows up on an ECG as steep peaks and valleys that are very close together. If left untreated, ventricular tachycardia can degenerate into ventricular fibrillation (VF or V-Fib), which shows up as smaller, uneven, disorganized peaks and valleys.

**Figure 17-7** An ECG tracing of normal sinus rhythm.
Blood Pressure

The blood pressure is the amount of pressure exerted against the arterial wall during circulation. The systolic blood pressure is the measured force exerted during the contraction of the heart, whereas the diastolic blood pressure is the pressure inside the artery when there is no contraction, or between contractions of the heart. The vessel’s size plays a major role in the blood pressure. A smaller-sized vessel will offer greater resistance, resulting in a higher pressure. Thus, vasoconstriction (constriction of the vessels) will increase vessel resistance and blood pressure. Conversely, the larger the vessel size, the lesser the amount of resistance and the lower the blood pressure. Vasodilation (dilation of the vessels) will cause the resistance to decrease and the blood pressure will fall.

Inadequate Circulation

A properly functioning circulatory system delivers oxygen and nutrients to the body’s cells and carries away carbon dioxide and other wastes. These processes take place as blood passes through the capillaries. The delivery of oxygen and nutrients from the blood through the thin capillary walls into the cells, and the removal of carbon dioxide and other wastes, is known as perfusion.

Under some conditions, blood does not circulate adequately through all the body’s capillaries. The chief result of inadequate circulation is a state of profound depression of cell perfusion, called shock (or hypoperfusion), as described in Chapter 15, “Shock and Resuscitation.” The cells become starved for oxygen (hypoxia) and nutrients and become overloaded with carbon dioxide and other waste products.

Hypoperfusion can occur as a result of low blood volume (hypovolemia), insufficient pumping action of the heart (heart failure), or dilated vessels (vasodilation) that may also be leaking. Hypoperfusion from massive vasodilation can also be caused by spinal cord damage that interrupts innervation of the blood vessels. In the absence of stimulation, the smooth muscle in the blood vessels relaxes, which results in massive dilation of the blood vessels, creating a vascular system that is too large overall for the amount of available blood. A more detailed discussion of hypoperfusion and its causes and consequences can be found in Chapter 15, “Shock and Resuscitation.”

Atherosclerosis

To better understand the signs and symptoms of cardiac compromise, it is important to learn some of the basic disease processes related to these conditions. Atherosclerosis is a condition that causes the smallest of arterial structures to become stiff and less elastic. This is often referred to as “hardening of the arteries.” A form of arteriosclerosis is atherosclerosis. Atherosclerosis is a systemic arterial disease. Its name is derived from the Greek word atheré, meaning “gruel” or “porridge,” and sclerosis, which means “hard.” It is the underlying pathogenic process in the majority of patients that have coronary artery disease that causes myocardial infarctions as well as the arterial changes that result in stroke. Atherosclerosis alone is the number one killer worldwide, in economically developed countries.

Atherosclerosis is an inflammatory disease that starts with the intimal (innermost) lining of the blood vessels,
where endothelial cells become damaged. Common risk factors that are thought to cause this endothelial injury include smoking, diabetes, hypertension, high levels of low-density lipoproteins (LDLs), and low levels of high-density lipoproteins (HDLs).

Once injury occurs, intimal changes and inflammation progress through the following basic pathophysiological events:

- Damage to the intima lining in the vessel allows the movement of blood platelets and other substances in the blood (serum lipoproteins) into the vascular wall. This irritates and inflames the vascular wall.
- As a result of the irritation and inflammation, different types of cells travel to the location, as do smooth muscle cells of the tunica media layer (muscular middle layer of the blood vessel).
- As these cells proliferate, fatty streaks develop in a longitudinal pattern in the lumen (inner opening) of the blood vessels. The blood vessel weakens as the intima and media layers are deprived of nutrients from the expanding plaque.
- In an attempt to “close off” the fatty streaks, smooth muscle cells produce collagen that covers the fatty streak to form a fibrous cap.
- Fibrous caps, however, are not stable and may rupture. The body views the rupture as an injury, which causes the body’s clotting mechanism to activate. The development of a thrombus (clot) may occlude the blood vessel.

This progression of vascular disease ties together many of the cardiac, pulmonary, and neurological emergencies seen in the prehospital environment. Although this disease process can affect all arteries in the body, it is not until there is a resulting specific organ dysfunction that the damaging effects to the body become obvious.

When a patient has a buildup of fatty deposits (atherosclerosis) on the inside of the coronary arteries, the condition is called coronary artery disease (CAD). The narrowing of the coronary blood vessel increases the resistance to blood flow through the artery and decreases the amount of blood flow to the distal heart muscle. The fatty deposits reduce the coronary arteries’ ability to dilate (become larger) and deliver additional blood flow to the heart when needed, such as in an increase in heart rate or more forceful pumping action.

#### Acute Coronary Syndrome

**Acute coronary syndrome (ACS)** results from a variety of conditions that can affect the heart in which the coronary arteries are narrowed or occluded by fat deposits (plaque), clots, or spasms. The word *acute* refers to a sudden onset, coronary refers to a condition affecting the coronary arteries, and syndrome indicates a group of signs and symptoms produced by the condition. Two conditions that are part of any acute coronary syndrome are unstable angina and myocardial infarction (heart attack). A heart muscle that is not receiving an adequate amount of oxygenated blood because of narrowing of the coronary arteries by plaque or spasms, clot formation inside the coronary artery blocking the blood flow, an increase in the work of the heart that demands more blood flow than can be supplied through the coronary arteries, or any combination of these, results in cardiac cell hypoxia, also known as myocardial ischemia. The prefix *myo-* refers to muscle and cardiac refers to the heart. *Ischemia* refers to a deficient supply of oxygenated blood. Myocardial ischemia is a state in which there is inadequate delivery of oxygen to the heart muscle.

The typical response of the heart to ischemia is chest discomfort, commonly referred to as “chest pain” by many health care professionals, although the patient normally refers to the sensation as more of a feeling of discomfort rather than pain. Chest discomfort or pain that is a result of heart muscle ischemia is referred to as ischemic-type chest pain. However, you may ask the patient if he is experiencing “chest pain” and he may answer “no.” More often, the patient feels a crushing chest pressure that is described as “dull and aching” and not as “pain.” The pain or discomfort may be localized to the area of the sternum and radiate to the jaw, arms, shoulders, or back—which is considered the “typical” chest discomfort in cardiac compromise—or it may be a diffuse chest or back discomfort or ache. Any time you are collecting a history on a patient suffering a suspected cardiac compromise, it is most appropriate to ask if the patient is experiencing “chest discomfort” and not chest pain.

**Angina Pectoris**

Angina pectoris (which means, literally, “pain in the chest”) is a symptom commonly associated with coronary artery disease. Many patients suffer from angina-type pain. Classic angina typically occurs upon an increased workload placed on the heart. This may be from an increase in the heart rate or contractile function. *Unstable angina* has a variety of definitions, but usually indicates angina discomfort that is prolonged and worsening, or that occurs without exertion and when the patient is at rest.

**Pathophysiology.** Angina pectoris is a symptom of inadequate oxygen supply to the heart muscle, or myocardium (Figure 17-8). As noted earlier, it results from a decrease in oxygen delivered to the myocardium, which is often caused by partial blockage of the coronary arteries, which causes ischemia (reduced delivery of oxygenated blood) that, in turn, results in tissue hypoxia (oxygen deficiency in the tissues). The lack of oxygen causes the discomfort, sometimes described as “crushing,” or “squeezing,” or as a “tightness” by the patient.

Generally, angina pectoris occurs during periods of stress, either physical or emotional. Once the stress is relieved or removed or the patient rests, the pain will usually go away. The pain is usually felt under the sternum...
and may radiate to the jaw, down either arm, to the back, or to the epigastrium (upper center region of the abdomen). The pain usually lasts for about 2–15 minutes. Many patients will be able to tell you that they have had angina as part of their past medical history and will have nitroglycerin prescribed for this condition. Prompt relief of the symptoms after rest and administered nitroglycerin is typical of angina.

**Assessment.** The signs and symptoms of angina pectoris (Figure 17-9 ■) are similar to those of any cardiac compromise and may include the following:

- Steady discomfort, usually located in the center of the chest but may be more diffuse throughout the front of the chest
- Discomfort that is usually described as pressure, tightness, aching, crushing, or heavy
- Discomfort that may radiate to the shoulders, arms, neck, jaw, back, or epigastric region (upper center abdomen)
- Cool, clammy skin
- Anxiety
- Dyspnea (shortness of breath)
- Diaphoresis (excessive sweating)
- Nausea and/or vomiting
- Complaint of indigestion pain

Women, diabetics, and the elderly may not have the typical presentation of signs and symptoms of angina. The discomfort may appear to be more diffuse or may be described more vaguely. These patients may not have any chest pain or discomfort but may instead complain of shortness of breath, fainting, weakness, or lightheadedness.

Classic angina is typically relieved with rest and nitroglycerin. If the classic angina following exertion is not relieved after rest or after three nitroglycerin tablets or sprays over a 10-minute period, you should recognize this as an acute coronary syndrome emergency and provide prompt treatment and transport.

**FIGURE 17-9** Both myocardial infarction and less serious angina can present symptoms of severe chest pain. Treat all cases of chest pain as cardiac emergencies.
Characteristics of unstable angina may include pain or discomfort that occur at rest, is continuing without relief, or is prolonged. If the patient experiences angina that occurs at rest and lasts for greater than 20 minutes, angina with a recent onset that is getting progressively worse, or angina that wakes the patient at night (nocturnal angina), you should view it as an acute coronary syndrome emergency and provide prompt treatment and transport.

**Emergency Medical Care.** Emergency care for the patient suffering from angina should be provided whether signs and symptoms of an acute coronary syndrome emergency exist or not. You should establish an open airway. If the patient’s respirations become inadequate, begin positive pressure ventilation. Apply the pulse oximeter, if available, to monitor the oxygen level. According to the AHA 2010 guidelines, administer supplemental oxygen if the patient is dyspneic, hypoxemic, has obvious signs of heart failure, has an SpO₂ reading of <94%, or the SpO₂ is unknown. Administer oxygen via a nasal cannula at 2 to 4 lpm and titrate the concentration and liter flow to achieve and maintain an SpO₂ of ≥94%. The AHA 2010 guidelines indicate that there is not sufficient evidence to support the use of supplemental oxygen as a routine in patients who do not present with dyspnea, hypoxemia, heart failure, or an SpO₂ of <94%.

If the patient has prescribed nitroglycerin and his systolic blood pressure is greater than 90 mmHg, place him in a sitting or lying position and administer the nitroglycerin tablets or spray. If the patient is suspected of suffering from a coronary artery occlusion, administer 160–325 mg of aspirin if your local protocol allows it. Consider contacting advanced life support and be prepared to manage a cardiac arrest patient. Continue to perform a reassessment.

**Acute Myocardial Infarction**

An acute myocardial infarction (AMI) occurs when a portion of the heart muscle dies because of the lack of an adequate supply of oxygenated blood. Aute means sudden, myocardial refers to heart muscle, and infarction refers to death of tissue. An acute myocardial infarction is what the layperson refers to as a heart attack.

**Pathophysiology.** An acute myocardial infarction typically is the result of coronary artery disease that causes severe narrowing or complete blockage of the coronary arteries. A plaque erosion or rupture within the coronary artery may cause the narrowing and blockage to occur. The end result is a portion of heart muscle that does not receive an adequate supply of oxygenated blood. After about 20–30 minutes without adequate perfusion, the heart muscle begins to die. Rarely, a heart attack could also result from a spasm of the coronary artery. This can be caused by use of a drug such as cocaine.

When the blood flow is blocked, the heart muscle becomes ischemic (hypoxic from inadequate oxygenation). If the blood flow is not restored to that portion of heart muscle, the cells will begin to die. Ischemic heart tissue will become irritable. It may produce abnormal beats in the conduction system that could lead to dysrhythmias. Some dysrhythmias, such as ventricular fibrillation and ventricular tachycardia, may be fatal. Ventricular fibrillation, which is the most common dysrhythmia the patient will suffer initially in cardiac arrest, will usually occur within the first hour after the onset of the symptoms of a heart attack.

With the availability of techniques to re-establish blood flow in the coronary artery by mechanically increasing the internal lumen size and medications called fibrinolytics and antiplatelet agents, commonly referred to as “clot busters,” it may be possible to dissolve the clot, reopen the coronary artery, and restore perfusion to the ischemic heart muscle. Prompt recognition and transport is necessary, since the window of time to mechanically open the vessel or to administer the fibrinolytics is limited.

**Assessment.** Chest discomfort is the most significant symptom of a heart attack. The discomfort the patient experiences is similar to that of angina; however, the symptoms last longer. Also, chest discomfort from an acute myocardial infarction will be only partially relieved with nitroglycerin or not relieved at all. The boundaries between unstable angina and AMI are not so distinct, and it may be difficult to distinguish between the two conditions.

Signs and symptoms of AMI (review Figure 17-9) include the following:

- Chest discomfort radiating to jaw, arms, shoulders, or back
- Anxiety
- Dyspnea
- Sense of impending doom
- Diaphoresis
- Nausea and/or vomiting
- Light-headedness or dizziness
- Weakness

Remember that diabetics, the elderly, and women are more prone to an atypical (not typical) presentation of symptoms when suffering a heart attack. Many may suffer a “silent MI” in which no chest discomfort is experienced. They may complain only of shortness of breath, nausea, light-headedness, or weakness.

**Emergency Medical Care.** When the signs and symptoms of an acute myocardial infarction are present, you should proceed rapidly with your assessment and management of the patient. This patient has the potential to go into cardiac arrest; therefore, you should frequently assess the patient and maintain a vigilant watch over the patient’s condition. If at all possible, the patient should never be left alone while you are returning equipment to the EMS unit or retrieving and preparing...
Aortic Aneurysm or Dissection

The aorta is the main trunk of the arterial system of the body, carrying blood pumped from the left ventricle of the heart. Branches of the aorta supply blood to the head, neck, and arms before the aorta turns downward through the thorax and abdominal cavity from which arteries branch off to the lower regions of the body.

Two types of life-threatening injuries may occur to the aorta that are often confused with each other: aortic aneurysm and aortic dissection. Both can cause pain that may be confused with the pain of myocardial infarction. Both occur more often in men than in women. However, aortic aneurysm and aortic dissection have distinctly different causes, signs, and symptoms.

Aortic aneurysm occurs when a weakened section of the aortic wall, usually resulting from atherosclerosis, begins to dilate or balloon outward from the pressure exerted by the blood flowing through the vessel. An aneurysm may exist for a long time with no symptoms or signs that the patient is aware of, then suddenly rupture, causing rapid and fatal internal bleeding (Figure 17-10). Aortic aneurysms occur most often in the abdominal region. Pain may be felt, especially in the back, when the aneurysm gets large enough, perhaps shortly before rupture occurs. Usually, the aorta cannot be felt on physical examination, but at this final stage it may be felt as a pulsating mass in the abdomen, although this may be difficult or impossible to detect in a heavy-set patient.

Aortic dissection occurs when there is a tear in the inner lining of the aorta and blood enters the opening and causes separation of the layers of the aortic wall (Figure 17-11). Aortic dissections occur most often in the area of the thorax. The pain is classically most severe when the dissection first occurs and is most often described as “sharp” pain, or sometimes as a “tearing” or “ripping” pain, often felt in the back, flank, or arm. Syncope may be the only sign in some patients. Depending on the location of the dissection along the aorta, it may cause symptoms similar to stroke or to myocardial infarction and, in fact, may lead to a myocardial infarction.
or other damage to the heart. A difference of 20 mmHg or greater in the systolic blood pressure reading between the upper arms or a severe decrease or difference in the upper and lower extremity pulse amplitude as compared to central pulses in a patient complaining of back or sharp chest pain should cause you to suspect a possible aortic dissection.

If a pulsating mass is felt and aortic aneurysm is suspected, administer oxygen and transport the patient immediately, as only surgery can prevent or repair rupture of the aneurysm. For a chest or back pain that may result from an aortic dissection or that may be a symptom of myocardial infarction, administer oxygen and assist the patient with prescribed nitroglycerin if the blood pressure is greater than 90 mmHg and no signs of hypovolemia are present. If aortic dissection is suspected, do not administer aspirin.

**Acute Coronary Syndrome in Females**

Of special concern is the presentation of myocardial ischemia or infarction in females. Almost all common descriptions of how an acute coronary syndrome presents clinically have been taken from male cases. This is in part because medical literature at one time described only males with ACS, because they were primarily the ones who suffered cardiac events. However, as females have gained a more prominent presence in the workforce, higher rates of smoking, poor nutrition habits, higher stress levels, and so forth, they are now suffering from heart attacks at rates approaching the rates among males. Coronary heart disease in females is now the single largest cause of death of females in the United States. In fact, since the incidence of myocardial infarctions in females is greater at older ages than in males, females are almost twice as likely to die from a myocardial infarction or its complications within the first few weeks following the event. The female may present with different signs and symptoms from a male when she is experiencing a cardiac event; however, the event is just as dangerous and can be as deadly. Therefore, the EMT must recognize some of the more subtle signs and symptoms that females suffering from acute coronary syndromes experience.

The following list of symptoms is common for females suffering from a cardiac ischemia or infarction. Although some descriptions are the same as for males, many others are not:

- **“Classical” findings (not necessarily common findings)**
  - Dull substernal chest pain or discomfort
  - Respiratory distress
  - Nausea, vomiting
  - Diaphoresis
- **“Nonclassical” or “atypical” findings (not necessarily uncommon findings)**
  - Neck ache
  - Pressure in the chest
  - Pains in the back, breast, or upper abdomen
  - Tingling of the fingers
  - Unexplained fatigue or weight gain (water weight gain)
  - Epigastric pain
  - Nausea and vomiting
  - Insomnia

Since the death rate for females who suffer heart attacks is higher than males when the event occurs, the EMT should have a high index of suspicion of ACS when gathering a history from the female patient. Err on the side of the patient and provide emergency care for a potential myocardial infarction or ACS, despite a presentation of “atypical” signs of ischemia or infarction.

Note that diabetics and the elderly are also high-risk groups that may present with atypical findings.

**The Dangers of Administering Too Much Oxygen in Acute Coronary Syndrome**

Oxygen was once thought to be helpful to all patients in all situations. Based on the most current research, it is clear that oxygen still has tremendous benefits; however, it is also clear that oxygen can be harmful and increases the amount of cell damage and death in certain situations. This is especially true in conditions in which tissue becomes ischemic from a lack of perfusion and oxygen is then reintroduced by restoring blood flow.

One such condition is acute coronary syndrome in which a coronary artery is occluded and cuts off blood supply to a distal area of heart tissue. This area of tissue becomes ischemic from the lack of oxygenated blood. During this period, there is an inflammatory response and the release of damaging molecules made from oxygen, which are referred to as free radicals.

The restoration of blood to an area of tissue that was once ischemic from low blood flow or occlusion of a vessel is called reperfusion. The oxygen in the blood flowing to the reperfused tissue increases the production of oxygen-free radicals. The free radicals directly damage cell membranes and other cellular components and result in cell death. This is called reperfusion injury.

To summarize: Higher oxygen levels in the blood result in an increase in the production of damaging free radicals and greater cell and tissue death. This occurs not during the hypoxic state but rather when blood flow has been restored and the cells are receiving oxygen again. The heart along with the brain, kidneys, liver, lungs, and intestines are highly sensitive organs affected by the production of free radicals during reperfusion. Keeping in mind the injurious processes that occur to tissues undergoing reperfusion, it makes sense that supplying more oxygen causes greater tissue damage.

Of course, in managing the acute coronary syndrome patient, it is necessary to reverse any hypoxia. However, it is also extremely important while reversing...
the hypoxia not to deliver more oxygen than is needed in order to avoid creating unnecessary cell damage. Therefore, it is recommended that oxygen be provided only to acute coronary syndrome patients with an SpO₂ <94%, or if an SpO₂ is unknown, or if the patient is dyspneic, hypoxic, or has obvious signs of heart failure.

To limit its concentration in the blood, oxygen should be administered via a nasal cannula starting at 2 lpm with just enough administered to reverse the hypoxia. It may be necessary to increase the liter flow to reach an SpO₂ of 94%. Once the SpO₂ reaches 94%, the liter flow should be maintained or adjusted to keep the SpO₂ at 94%.

Remember: Hyperoxigenating the acute coronary syndrome patient may lead to greater cardiac cell damage and death.

Other Causes of Cardiac Compromise

Heart Failure

When the heart no longer has the ability to adequately eject blood out of the ventricle, it is considered to be failing. The heart failure may be a result of a heart attack that affected a large portion of muscle because, when the heart muscle dies, it no longer contributes to the pumping function of the heart. Heart failure may also be caused by a valve disorder, hypertension, pulmonary embolism, cardiac rhythm disturbances, and certain drugs.

Pathophysiology. Heart failure can be categorized as left ventricular failure or right ventricular failure. The consequences of left or right ventricular failure can be understood by recalling the functions of the two sides of the heart: The left side of the heart receives oxygenated blood from the lungs and sends it out to the body’s arteries, while the right side of the heart receives deoxygenated blood from the body’s veins and sends it to the lungs to pick up oxygen.

Left ventricular failure occurs when the left ventricle cannot pump blood out of the left ventricle effectively (Figure 17-12). This reduces blood flow to the arteries and the perfusion of blood to the cells throughout the body. Furthermore, blood waiting to enter the left ventricle from the left atrium and blood waiting to enter the left atrium from the lungs backs up in a sort of “traffic jam.” When the left ventricle fails to eject the normal amount of blood with each contraction, the blood pressure begins to build up in the left atrium. The increase in pressure in the left atrium, in turn, causes an increase in pressure in the pulmonary veins, which are responsible for delivering blood from the lungs to the heart. The increase in pressure in the pulmonary veins creates a higher pressure in the capillaries in the lungs. Remember that the capillaries in the lungs are the sites of gas exchange with the alveoli. When the pressure in the capillaries is increased, fluid begins to leak out between the capillary and the alveoli. The fluid collects between the capillary and around the alveoli and distal bronchioles. This causes the space between the capillary and the alveoli to widen, making gas exchange more difficult. The poor gas exchange leads to hypoxia. This condition is referred to as pulmonary edema.

When the right side of the heart fails, the blood backs up into the venous system. The right side of the heart may fail due to failure of the left ventricle. It may also fail due to hypertension (high blood pressure). Chronic obstructive pulmonary disease (COPD) may increase the pressure in the pulmonary vessels in the lungs and cause the right ventricle to work much harder. Over time, this may cause the right ventricle to fail. Signs include peripheral edema, jugular vein distention, and liver enlargement.

Another problem than can occur with left or right heart failure is a condition known as cardiogenic shock. This is a clinical state (not a diagnosis) in which the left or right ventricle fails to pump out enough blood to meet the demands of the body. The most common cause for this is myocardial damage that occurs secondary to a heart attack. Other less common reasons include sustained hypertension, valve damage, extremes in heart rate (too fast or too slow), and other cardiac muscle diseases (cardiomyopathies). Cardiogenic shock can be from the pumping inadequacy of either the left or right ventricle.

When the left ventricle fails, the cardiac output drops and there is a diminishment in the perfusion pressure to the rest of the body’s organs. Common findings include a drop in systolic blood pressure (to include frank hypotension), diminished or absent peripheral pulse amplitude, altered mental status, changes in the heart rate, poor urinary output, respiratory distress, inspiratory rales, and possible pulmonary edema.

The right ventricle can also fail for any of the same reasons as the left, but has slightly different presentation. Remember that the right ventricle pumps blood to the lungs for reoxygenation. If the right-sided cardiac output starts to drop, then the lungs may be hypoperfused,
which can lead to hypoxia and respiratory distress. Also, as the blood starts to accumulate in the ventricle from poor ejection, it will eventually back up into the atrium and subsequently into the vena cava. Findings of this may include jugular venous distension and peripheral edema. One other change in normal physiology is that if the right side is pumping inadequately, then the left side of the heart will receive an insufficient amount of blood. Since the left ventricle can only pump as much blood as it receives, the patient may also display many of the aforementioned findings of poor peripheral perfusion. There is, however, a triad of findings that may help delineate pure left heart failure from pure right heart failure. They are identified in Table 17-1.

*Congestive heart failure (CHF)* is a medical diagnosis that refers to the condition in which there is a buildup of fluid (congestion) in the body resulting from the pump failure of the heart. In essence, it represents the condition in which the left, the right, or both ventricles are failing to meet the body’s needs. It may be a chronic condition that presents over a period of time, or it may be more acute, as associated with a large heart attack that affects the left ventricle. Congestive heart failure commonly leads to pulmonary edema and edema (swelling) in other areas of the body. The edema will often be seen in the feet and ankles, the hands, and the presacral area (lower lumbar region) of the supine patient. The fluid may also accumulate in the liver, causing it to enlarge, and also in the abdomen. When fluid collects in the abdomen, the abdomen may become distended and feel like a sponge. Often, these patients will sit upright and dangle their legs, feet, arms, and hands so that the blood can pool in the extremities and lessen the amount the heart has to pump out.

**Assessment.** The signs and symptoms of heart failure depend on the severity of the condition and whether it is an acute-onset or a long-term problem (Figure 17-13 ■). The signs and symptoms of heart failure include the following:

- Marked or severe dyspnea (shortness of breath)
- Tachycardia (rapid heart rate greater than 100 bpm)
- Difficulty breathing when supine (orthopnea)
- Suddenly waking at night with dyspnea (paroxysmal nocturnal dyspnea)
- Fatigue on any type of exertion
- Anxiety
- Tachypnea (rapid respiratory rate)

### Table 17-1

<table>
<thead>

**Signs and Symptoms of Congestive Heart Failure**

- Mild to severe confusion.
- Cyanosis.
- Tachypnea.
- May cough up pink sputnum.
- Low, normal, or high blood pressure.
- Rapid heart rate.
- A desire to sit upright.
- Anxiety.
- Distended neck veins. (Late)
- Crackles.
- Shortness of breath (dyspnea).
- Pale, cool, clammy skin.
- Abdominal distention.
- Pedal and lower extremity edema.

**Figure 17-13** Signs and symptoms of congestive heart failure.
• Diaphoresis (sweating)
• Upright position with legs, feet, arms, and hands dangling
• Cool, clammy, pale skin
• Chest discomfort
• Cyanosis
• Agitation and restlessness due to hypoxia
• Edema (swelling) to the hands, ankles, and feet (Figure 17-14 ■)
• Crackles and possibly wheezes on auscultation
• Decreased SpO₂ reading
• Signs and symptoms of pulmonary edema
• Blood pressure may be normal, elevated, or low
• Distended neck veins—jugular venous distention (JVD) (late) (Figure 17-15 ■)
• Distended and soft spongy abdomen

Commonly, these patients will tell you that they are taking a “water pill.” This is a diuretic that is used to reduce the amount of fluid in the body. They may also be on other drugs to strengthen the force of contraction of the heart and reduce the response of the sympathetic nervous system.

**Emergency Medical Care.** The treatment for the patient with heart failure is basically the same as for the patient with an acute myocardial infarction. Ensure the patient has a patent airway. Provide positive pressure ventilation with supplemental oxygen connected to the device if the breathing is inadequate.

The heart failure patient with pulmonary edema will benefit significantly from positive pressure ventilation. It will increase the effectiveness of gas exchange by forcing the oxygen to cross over the alveoli and the space between the alveoli and the capillary. You may see drastic improvement in the patient’s condition following positive pressure ventilation. If the patient will tolerate positive pressure ventilation and medical direction allows it, attempt to provide ventilation early.

If the patient has an adequate respiratory rate and tidal volume, administer supplemental oxygen. According to the AHA 2010 guidelines, administer supplemental oxygen if the patient is dyspneic, hypoxemic, has obvious signs of heart failure, has an SpO₂ reading of <94%, or the SpO₂ is unknown. Administer oxygen via a nasal cannula at 2 to 4 lpm and titrate the concentration and liter flow to achieve and maintain an SpO₂ of >94%. Apply a nonrebreather mask at 15 lpm if severe hypoxia is present. If pulmonary edema is present or the patient is in moderate to severe respiratory distress, consider the use of continuous positive pressure ventilation (CPAP) if he meets the indications and criteria for its use. Follow your local protocol.

If the patient has chest discomfort and has a prescription for nitroglycerin, administer one tablet every 3–5 minutes to a total of three tablets. Follow your local protocol. Nitroglycerin will also be beneficial to the patient by reducing the pressure in the arteries of the body, making it easier for the left ventricle to pump the blood out. Any venous dilation will cause less blood to return to the heart and reduce the workload of the ventricles. Ensure that the patient has a systolic blood pressure of greater than 90 mmHg prior to administration of nitroglycerin.

Continuously assess the patient and be prepared for respiratory failure and cardiac arrest. Be sure to let the patient assume a position of comfort. Never force the patient to lie flat, since this will commonly worsen the dyspnea.

**Hypertensive Emergencies**

A hypertensive emergency is defined as a severe, accelerated hypertension episode with a systolic pressure greater than 160 mmHg, and/or a diastolic blood pressure greater than 94 mmHg. Hypertension usually does not produce any clinical findings until there are vascular
changes to the heart, brain, lungs, or kidneys. Although hypertension is a common finding in the United States, affecting about 25 percent of the population, episodes of hypertensive emergencies are, fortunately, rare. This is an important point to note. For example, a patient with chronic hypertension may be experiencing a stroke, and you are summoned to care for the stroke, not the elevation in blood pressure. It is just coincidental that the patient’s blood pressure is up (which in that situation is “normal” for him). Conversely, if a rapid increase in blood pressure occurs to a patient who does not have chronic elevations, he may present with signs and symptoms related directly to the hypertensive crisis. It is key to ascertain a thorough patient history in these patients to help make that decision.

Pathophysiology. There are two types of hypertensive patients, those with “primary” hypertension and those with “secondary” hypertension. Primary hypertension is most common, and is characterized by a hypertensive state in which no specific cause for the hypertension has been identified (idiopathic), although theories do exist as to the cause. The patient with primary hypertension most likely will be taking medications designed to keep the blood pressure low, and be on a diet that limits certain foods such as sodium. “Secondary” hypertension is said to occur when a patient is hypertensive from some other underlying disease process. For example, patients with renal disease are usually chronically hypertensive, as are patients with certain thyroid disorders.

Regardless of the cause, it is important for the EMT to ascertain from the patient if he has chronic elevations in his blood pressure. If he does, chances are that he has his blood pressure tracked and documented on a card that he carries with him. The EMT should only evaluate his current blood pressure in light of what a “normal” blood pressure is for him. For example, a patient may be experiencing a seizure but coincidentally has a diagnosis of high blood pressure that he takes medicine for. A normal blood pressure for him might be 168/90 mmHg. If his actual blood pressure during this emergency is near his average blood pressure, then the EMT should focus treatment on the seizure, and not the blood pressure itself. However, if a patient is found to be experiencing a seizure, but his normal blood pressure is 110/60 mmHg, and you find that his current blood pressure is 168/90 mmHg, then the blood pressure must be considered during the assessment as a possible etiology or sign of a condition causing the seizure such as stroke.

Assessment. If the patient has the signs and symptoms listed next, with a blood pressure consistent with his normal blood pressure, treat the underlying cause. If the patient’s blood pressure is significantly higher than his normal blood pressure, consider the findings to be related to the hypertension. Signs and symptoms of a hypertensive emergency are:

- Severe headache
- Ringing in the ears
- Nausea and/or vomiting
- Elevated blood pressure
- Respiratory distress
- Chest pain
- Seizures
- Focal neural deficits
- Indications of organ dysfunction (stroke, heart attack, pulmonary edema)
- Possible nosebleed

Emergency Medical Care. In the prehospital setting, it is difficult to differentiate an emergency produced by hypertension from an emergency that presents with hypertension but has a different cause. It is difficult to make these distinctions without diagnostic tests that are available in the emergency department. Nevertheless, always remember to support lost functions to the airway, breathing, oxygenation, and circulation in any of these patients.

Oxygen administration should be guided by the SpO2 reading, signs and symptoms of a possible underlying condition, and signs of hypoxia in a patient with adequate breathing. Administer supplemental oxygen if the patient is dyspneic, hypoxemic, has obvious signs of heart failure, has an SpO2 reading of <94%, or the SpO2 is unknown. Administer oxygen via a nasal cannula at 2 to 4 lpm and titrate the concentration and liter flow to achieve and maintain an SpO2 of >94%. If the patient is breathing inadequately, positive pressure ventilation should be initiated immediately at a rate of 10–12 per minute with supplemental oxygen applied to the ventilation device.

The patient should also be placed in a position of comfort, but encourage a semi-Fowler’s position if there are no airway concerns. Consider contacting ALS for backup or intercept as medications do exist to lower the elevated blood pressure should the patient meet certain criteria. If you suspect the hypertensive patient might be having a stroke, the blood pressure will not be lowered in the prehospital setting; thus, it may not be prudent to delay transport to wait for ALS. Finally, provide emotional support and reassurance while transporting the patient.

Cardiac Arrest

Cardiac arrest is the worst manifestation of cardiac compromise from an acute coronary event. It occurs when the heart, for any of a variety of reasons, is not pumping effectively or at all, and no pulses can be felt. As discussed previously, the primary risk factor for an acute coronary syndrome is coronary artery disease. Although cardiac arrest is commonly caused by an acute coronary syndrome, it can also be caused by a myriad of other conditions. For example, a traumatized patient may be in arrest following severe multisystem trauma.
or significant blood loss. A person who accidentally or purposely overdoses on his medication may be in arrest as a result of the effects of the medication. Even a stroke or seizure patient may go into cardiac arrest secondary to the initial emergency. The EMT must remain acutely aware of the patient’s clinical status whenever he is unstable because any patient has the potential to go into arrest. For more detailed information on cardiac arrest, refer to Chapter 15, “Shock and Resuscitation.”

**NITROGLYCERIN**

While patients with known cardiac problems may be on a variety of medications, the most common will be nitroglycerin. Nitroglycerin is a potent vasodilator (agent that increases the diameter of blood vessels). It works in seconds to relax the muscles of the blood vessel walls. This action dilates arteries, increasing the blood flow through the coronary arteries and oxygen supply to the heart muscle and decreasing the workload of the heart.

**PATHOPHYSIOLOGY PEARLS**

Nitroglycerin dilates coronary arteries, peripheral arteries, and veins, causing an increase in coronary artery blood flow, a decrease in peripheral vascular resistance, and a decrease in the myocardial workload.

Nitroglycerin can be in the form of either a sublingual (under-the-tongue) tablet or a sublingual spray. A paste form of nitroglycerin is also available, but it is not considered appropriate for administration by an EMT, because the onset of action is too long.

If the patient with a history of heart problems is suffering from cardiac-related chest pain and has nitroglycerin that has been prescribed for him by a physician, you may assist the patient in taking this medication after receiving authorization from medical direction. Because nitroglycerin lowers blood pressure, it must not be given to a patient whose systolic blood pressure is less than 90 mmHg or no more than 30 mmHg lower than the baseline systolic blood pressure. Also, have the patient lie or sit down prior to administration. Do not administer the nitroglycerin to a patient with extreme bradycardia (<50 bpm) or tachycardia (>100 bpm). Follow your local protocol when considering the administration of nitroglycerin. If the patient has taken tadalafil (Cialis), vardenafil (Levitra), or sildenafil (Viagra) within the last 48 hours, do not administer nitroglycerin because it may cause a potentially fatal drop in systolic blood pressure. Follow your local protocol.

If the patient experiences no relief after one dose, another dose may be administered after 3–5 minutes if authorized by medical direction, to a maximum of three doses. Find out if the patient has already taken one or more doses prior to your arrival to be sure that you are not inadvertently administering more than the maximum.

**ASSESSMENT TIPS**

A systolic blood pressure of 90 mmHg or a systolic pressure that is 30 mmHg less than the patient’s baseline systolic pressure is a contraindication to the administration of any additional nitroglycerin.

Nitroglycerin will often produce a stinging or burning sensation under the tongue or may cause the patient to get a headache following administration. You may have heard that if the patient does not feel the stinging or burning, or does not get a headache, then the nitroglycerin is old and ineffective. This is not true. Just because the patient does not feel any of these sensations, it does not mean the nitroglycerin is no good. However, age and light will inactivate nitroglycerin tablets. The patients are commonly instructed to keep a fresh supply sealed in a bottle in a dark area. If the patient has a prescription for nitroglycerin, ask for the “fresh” supply and assist with the administration of the fresh nitroglycerin. Nitroglycerin spray may be good for up to 2 years. Some nitroglycerin may be working but appear to be ineffective because the coronary artery disease is so severe.

See EMT Skills 17-1 for information on how to assist a patient with prescribed nitroglycerin. See Figure 17-16 for a detailed summary of the criteria and techniques for the administration of nitroglycerin.

**AGE-RELATED VARIATIONS: PEDIATRICS AND GERIATRICS**

Patients who are at the age extremes (the very young and very old) can also experience an acute coronary event, but its presentation and etiology may be somewhat dissimilar than the typical adult patient. Remember that the skills and interventions employed on most adult cardiac arrest patients may not always be appropriate for some of these age-related variations. The goal of the following section is to introduce some of these idiosyncrasies that may be present in patients at the age extremes.

**Pediatric Considerations**

Pediatric patients do not typically have acute coronary syndromes such as a myocardial infarction or ischemic episode as adult patients do. (However, it is possible.) Typically when a pediatric patient experiences a cardiac disturbance, it is from some congenital heart condition that the family usually knows about. In these situations, it is best to contact medical direction as early as possible and seek advice about the best course of action for the pediatric patient experiencing a cardiac emergency secondary to a congenital heart condition. Whatever additional course of action is recommended, always remember to support any lost function to the airway, breathing, or circulation components of the body. See
Nitroglycerin is the generic name. Some of the trade names of nitroglycerin are:
- Nitrostat
- Nitro-Bid
- Nitrolingual Spray

**Indications**
All of the following criteria must be met before an EMT administers nitroglycerin to a patient:
- The patient exhibits signs and symptoms of chest pain.
- The patient has physician-prescribed nitroglycerin.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

**Contraindications**
Nitroglycerin should not be given if any of the following conditions exist:
- The patient's baseline systolic blood pressure is below 90 mmHg systolic or the systolic blood pressure has decreased greater than 30 mmHg from the baseline.
- The heart rate is less than 50 bpm or greater than 100 bpm.
- The patient has a suspected head injury.
- The patient is an infant or a child.
- Three doses have already been taken by the patient.
- The patient has taken tadalafil (Cialis), vardenafil (Levitra), or sildenafil (Viagra) within the past 24 hours.

**Medication Form**
Tablet, sublingual spray.

**Dosage**
The dosage for EMT administration of nitroglycerin is either one tablet or one spray under the tongue. The most commonly prescribed dose is either 0.3 mg per tablet (or metered spray), or 0.4 mg per tablet (or metered spray). Regardless of the individual dose unit, the administered dose may be repeated in 3–5 minutes if (1) the patient experiences no relief; (2) the blood pressure remains greater than 90 mmHg systolic or does not fall more than 30 mmHg below the baseline systolic pressure; (3) the heart rate remains above 50 bpm and below 100 bpm; and (4) medical direction gives authorization. The total dose is three tablets or sprays, to include what the patient took prior to your arrival.

**Administration**
To administer nitroglycerin (EMT Skills 17-1):
1. Complete the history and physical exam of the cardiac patient and determine that the patient has his own nitroglycerin. Be sure the patient is sitting or lying supine.
2. Assess baseline vital signs to ensure that the systolic blood pressure is greater than 90 mmHg or greater than 30 mmHg below the systolic baseline, and the heart rate is above 50 bpm and less than 100 bpm (follow local protocol).
3. Obtain approval from medical direction, either on-line or off-line, to administer nitroglycerin.
4. Check the patient’s medication to ensure that it is nitroglycerin prescribed in the patient’s name and to learn the dose and route of administration.
5. Be sure that the patient is alert and responsive.
6. Check the expiration date on the nitroglycerin.
7. Ask the patient when he took his last dose of medication and what its effects were. Also be sure that the patient understands how the medication will be administered.
8. Wear gloves when handling nitroglycerin. As the patient lifts his tongue, place or spray the medication under the tongue. Alternatively, have the patient place the tablet or spray under the tongue himself.
9. Remind the patient to keep his mouth closed and not to swallow until the medication has dissolved.
10. Perform a reassessment of the patient’s blood pressure in 2 minutes after the nitroglycerin administration, and before your next dose.
11. Record your actions, including the dosage, the time of administration, and the patient’s response.

**FIGURE 17-16** Nitroglycerin.
Chapter 38, “Pediatrics,” to learn more about pediatric emergencies related to the cardiovascular system.

Pediatric patients may also experience cardiac arrest, but its frequency is much lower than in adults, and the underlying cause is typically respiratory in nature, rather than cardiovascular as with the adult patient. Infants and children still have a healthy heart at a young age, and it is unlikely to fail. What typically puts a young patient into cardiac arrest is an emergency that leads to airway occlusion or ventilatory insufficiency. As the young patient becomes more and more hypoxic and acidotic, the heart will eventually fail and the patient will slip into cardiac arrest. Even with early and appropriate resuscitation, cardiac arrest survival rates for children are much lower than for adults, because the arrest typically occurred after a long period of hypoxemia, acidosis, and ventilatory insufficiency.

These facts underscore the importance for the EMT to remain vigilant about establishing and maintaining an airway in a pediatric patient as well as ensuring adequate ventilation. The best treatment for cardiac arrest in a pediatric patient is to prevent it entirely by ensuring an open airway, adequate breathing, and oxygen supplementation. See Chapter 38, “Pediatrics” to learn more about pediatric respiratory emergencies and cardiac arrest management.

Geriatric Considerations

Geriatric patients will represent the highest number of patients you treat who are experiencing some form of acute coronary syndrome. The emergency may be as minimal as mild respiratory distress and chest discomfort or as severe as full cardiopulmonary arrest. The EMT should remain alert for findings that could indicate acute deterioration in the geriatric population.

There may be some differences in presentation or management of these patients should an acute coronary event occur, or if they go into cardiac arrest, based on the patient’s medical history and current medical conditions. Table 17-2 outlines some of these considerations.

### ASSESSMENT AND CARE: GENERAL GUIDELINES

#### Assessment-Based Approach: Cardiac Compromise and Acute Coronary Syndrome

Dispatch information can provide you with the first indications that a patient may be suffering from cardiac compromise. When you are directed to patients complaining of chest pain or chest discomfort and/or difficulty in breathing, suspect the possibility of cardiac problems. Remember that any adult patient with chest pain or chest discomfort should be treated as a cardiac emergency until proven otherwise.

#### Scene Size-up

On arrival, perform the scene size-up to ensure that the scene is secure, and then proceed rapidly with the primary assessment.

---

**Drug Profile**

**Nitroglycerin continued**

**Actions**

- Dilates blood vessels
- Decreases workload of the heart
- Decreases cardiac oxygen demand

**Side Effects**

The aim of administering nitroglycerin is to dilate blood vessels in the heart, but blood vessels in other parts of the body are dilated as well. This dilation can cause:

- Headache
- A drop in blood pressure
- Changes in pulse rate as the body compensates for the changes in blood vessel size

**Reassessment**

Whenever you administer nitroglycerin to a patient, you must perform a reassessment. The following steps must be included:

- Monitor blood pressure frequently during treatment and transport.
- Question the patient about the effect of the medication on the relief of pain.
- Obtain approval from medical direction prior to readministration of the medication.
- Constantly monitor the airway and breathing status; if the breathing becomes inadequate, begin positive pressure ventilation with supplemental oxygen.
- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.

- If the medication has had no or little effect, consult medical direction to consider another dose.
- Document any findings during the reassessment.
Primary Assessment

Form a general impression of the patient and his mental status as you approach the scene. Generally, patients experiencing cardiac emergencies fall into two categories: (1) unresponsive patients with no respiration and no pulse (cardiac arrest) and (2) responsive patients who appear to be in minor, moderate, or severe distress.

When you encounter an unresponsive patient with no ventilations, or agonal respirations, and no pulse, immediately begin chest compressions followed by airway management and ventilation. (Note that this sequence—compressions, airway, breathing (CAB)—differs from the airway, breathing/oxygenation, circulation (ABC) sequence generally followed when indications of cardiac arrest are not present). Immediately initiate CPR beginning with chest compressions for about two minutes (which equates to five cycles of 30:2 for a lone rescuer).

Apply the AED as soon as it is available. Continue with chest compressions until the defibrillation pads are applied. The key to CPR is to limit the interruption of chest compressions; therefore, it may be necessary to work around the compressor until the AED prompts the EMT to “stand clear.” Follow the AED protocol. For cardiac arrest patients up to 8 years of age, it is highly desirable that the AED have a dose-attenuating system that will deliver a reduced shock. If a pediatric dose-attenuating system is not available, apply the adult AED and proceed with the AED sequence. (An expanded discussion of AED use is in Chapter 15.)

With responsive patients, first ensure adequate airway, breathing, oxygenation, and circulation. Note the patient’s skin color, temperature, and condition. Note also the type, location, and intensity of any pain and presence of other signs or symptoms related to acute coronary syndromes. Apply oxygen if any of these is present:

- Signs of respiratory distress or dyspnea
- Signs of hypoxia
- Signs or symptoms of heart failure
- Signs or symptoms of shock

According to the AHA 2010 guidelines, administer supplemental oxygen if the patient is dyspneic, hypoxic, has obvious signs of heart failure, has an SpO₂ reading of < 94, or the SpO₂ is unknown. Administer oxygen via a nasal cannula at 2 to 4 lpm and titrate the concentration and liter flow to achieve and maintain an SpO₂ of > 94%. Follow your local protocol.

Make a decision on whether early transport is needed and contact ALS as appropriate.

Secondary Assessment

Following the primary assessment, you will proceed with the secondary assessment.

History. If the patient has an altered mental status and is unable to answer questions appropriately, attempt to obtain history information from the family or bystanders at the scene. If the patient is able to answer questions appropriately, you will obtain a history from the patient and then proceed with the secondary assessment. As previously discussed, the information gained in the history of the medical patient provides the basis for further assessment and emergency care.

You should suspect that any patient complaining of chest discomfort, shortness of breath, fainting, general

<table>
<thead>
<tr>
<th>TABLE 17-2</th>
<th>Special Considerations in Geriatric Cardiac Events</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>History of diabetes mellitus</strong></td>
<td>A geriatric patient with diabetes has long-term damage to the nerve endings in the body. This causes the typical pain from an MI to be perceived poorly, if at all, by the diabetic patient. Therefore, the diabetic patient experiencing an MI may complain only of respiratory distress or dizziness when standing or even excessive weakness and dyspnea on exertion. It is important for the EMT to identify the patient with diabetes as potentially having an acute coronary event and to treat him appropriately. Contact ALS early, follow your local protocol, and ascertain if additional or alternative therapies are desired by medical direction.</td>
</tr>
<tr>
<td><strong>History of trauma</strong></td>
<td>If the geriatric patient is a trauma patient, there must be a high index of suspicion for cardiac involvement as well. Geriatric patients who are traumatized can slip quickly into cardiac arrest and do not respond well to typical interventions. Geriatric patients with head trauma, chest trauma, abdominal trauma, or extremity trauma with severe bleeding are especially susceptible to cardiac arrest.</td>
</tr>
<tr>
<td><strong>History of asthma</strong></td>
<td>If a patient with a history of asthma goes into cardiac arrest, the cause may be acute bronchoconstriction that led to hypoxemia, acidosis, and cardiac arrest. Until the bronchoconstriction is reversed, the patient will not regain a pulse or breathing. Early intercept or backup by an ALS unit will allow the administration of medications that may help reverse this condition.</td>
</tr>
<tr>
<td><strong>History of COPD</strong></td>
<td>Elderly patients commonly have some form of COPD (emphysema or chronic bronchitis). The arrest may have been caused by an exacerbation of the COPD, which led to hypoxemia, acidosis, and then arrest. ALS backup is needed during the resuscitation of this patient. Remember also that COPD disorders can weaken the lung tissue and cause the development of a pneumothorax and collapse of the lung. (This too may precipitate a cardiac arrest.) Be alert for the presence or the development of a pneumothorax during positive pressure ventilation, which may cause a bleb on the lung tissue to rupture.</td>
</tr>
</tbody>
</table>
weakness, or fatigue on exertion may be suffering from a possible cardiac compromise or an acute coronary syndrome. Obtain a history to identify information pertinent to the condition. When conducting a history of the chief complaint and other associated symptoms, such as chest discomfort and shortness of breath, use the OPQRST mnemonic to obtain the information. Chest discomfort is the most common chief complaint and most important signal of patients suffering from cardiac compromise and an acute coronary syndrome.

- **Onset.** What were you doing when the chest discomfort started? What triggered the discomfort? Was the onset sudden or gradual?

  There is a misconception that most acute coronary syndromes occur during physical exertion. According to the American Heart Association, only 10–15 percent occur during exercise or other physical activities. The majority of acute coronary syndromes occur at rest or with normal daily moderate activity. However, very strong emotional events such as death of a spouse, loss of a job, and divorce have commonly been experienced by those suffering a heart attack.

- **Provocation or palliation.** What makes the chest discomfort worse? What makes the chest discomfort better?

  Many patients with any type of acute coronary syndrome complain that the discomfort is made worse by exertion. Upon rest, the discomfort is completely relieved or it may have subsided to a lesser intensity. Some patients may complain of the discomfort at rest that worsens with any activity. Some chest discomfort is completely relieved after taking nitroglycerin, but, in worse conditions, the nitroglycerin provides only some relief or no relief of the chest discomfort. You may be called to the scene late at night for a patient who complains of chest discomfort that wakes him from his sleep. This may be a condition called nocturnal (refers to night) angina or it may actually be a heart attack.

- **Quality.** Describe the chest discomfort. Is it a dull, aching, pressure-type discomfort? Is it pressure, squeezing, crushing, or burning? Is it sharp or stabbing?

  The chest discomfort is most commonly described as a crushing pressure. It is also often described as dull, aching, squeezing, or burning. Many patients state, “It feels like someone is sitting on my chest.” Other patients present with their fist clenched over the center of their chest. This is called the Levine sign. It is an indication of severe chest discomfort. The chest discomfort may be described as being a more diffuse dull and aching-type sensation located in the back between the scapulae (shoulder blades). Again, it is important to ask about a “discomfort” and not just “pain.” Many patients may deny they are having pain, since the sensation is much more a feeling of pressure and not a true sharp or stabbing pain.

- **Radiation.** Does the discomfort radiate; that is, does it travel to any other part of the body? Do you feel it anywhere else in the body?

  Typically, in an acute coronary syndrome, the discomfort may radiate to the arms (most often the left arm), shoulders, jaw, epigastrium (upper middle portion of the abdomen just below the xiphoid process), neck, or back.

- **Severity.** On a 1-to-10 scale, with 10 being the worst, describe the discomfort.

  Remember that the 1-to-10 scale is subjective, since many patients have differing perceptions and tolerances for pain. Be sure to ask if the patient has ever experienced this pain previously. If the patient states that he had the same type of pain or discomfort in the past and was diagnosed with a heart attack, it is almost certain that the same presentation of discomfort or pain is due to another heart attack. If the patient presents with his fist tightly clenched over his chest, he is typically suffering from severe discomfort. Be sure to determine the severity both before and after rest and nitroglycerin.

- **Time.** When did the chest discomfort start? How long have you had the discomfort? Has the discomfort been constant or does it come and go (intermittent)?

  Because so many patients wait to seek help when experiencing chest discomfort, it may be necessary to determine the actual day and time the discomfort started if it started before the day the call was placed for EMS.

**Percutaneous Intervention (PCI) or Fibrinolytic Therapy and the EMT’s Role.** One advantage of interviewing the patient in the prehospital setting is the ability to gather information that is important to ongoing management of the patient in the hospital setting. Patient care for a myocardial infarction can be greatly enhanced if the hospital receives certain patient information necessary to make patient care decisions. With rapid removal of the clot by percutaneous intervention (also known as coronary angioplasty) or fibrinolytics, distal perfusion can be resumed and the extent of myocardial damage can be minimized or even inhibited. One concern with the fibrinolytics, however, is that they don’t just dissolve clots in the heart; they can dissolve clots no matter where they are located in the vessels of the body. For this reason, recent stroke patients, patients with a history of recent surgery, and similar patients cannot receive fibrinolytic drugs because of the risk that they may cause internal hemorrhage or other life-threatening complications. Therefore, percutaneous intervention (angioplasty) has become the most important consideration in the ST elevation MI patient.

As an EMT, you may be asked to complete a “fibrinolytic checklist” and present it to the emergency department staff as early as possible.

According to the AHA, fibrinolysis may be contraindicated if any of the following are present:

- Systolic or diastolic hypertension
- Recent head or facial trauma
Recent stroke or any history of bleeding within the cranium
- Pregnant patient
- Any recent trauma or surgery
- Recent history of gastrointestinal or genitourinary bleeding
- Patient taking blood thinners or one who has a clotting disorder
- History of cancer, kidney disease, liver disease or any other disease involving the central nervous system
- Suspected aortic aneurysm

Also, according to the AHA, if the patient has a heart rate > 100 bpm and a systolic BP <100 mmHg, signs of shock or pulmonary edema, has any contraindications to fibrinolysis, or required CPR, you should transport to a medical facility that has the capability of providing percutaneous coronary intervention (PCI) in the acute coronary syndrome patient. It is imperative that you follow your local protocol and use the local fibrinolytic checklist when making transport and destination decisions in acute coronary syndrome patients.

The use of percutaneous intervention (angioplasty) and fibrinolytics has made a significant impact on reducing the morbidity and mortality from acute coronary syndromes. The role of the EMT is to help identify those patients who may benefit from early percutaneous intervention or fibrinolytic therapy.

During your assessment of the patient with cardiac-related chest pain, you may find that a large number of patients, more often males than females, will make excuses as to why the chest discomfort they are experiencing is not a true heart attack. Many people claim the discomfort is nothing more than indigestion, so they take antacids. Many believe they are too healthy to suffer a heart attack. Others feel that if they indicate they are having chest discomfort it will frighten those in the household. Many do not want the embarrassment of having the fire department, First Responders, and EMS crews at their house. Others just feel that it cannot happen to them. This denial extends the period of time before people seek help when experiencing the symptoms of a heart attack. Remember that more than one-half of the patients who suffer a heart attack die outside of the hospital. A majority of those who die do so within the first hour of the onset of the symptoms of the heart attack.

Many times you will find that a family member, friend, or bystander take the initiative to place the call to EMS, and not at the patient’s request. Therefore, many patients will continue to downplay their symptoms. Some patients may be so convincing that not only do they convince themselves, their family, and bystanders, but they also convince the EMS crew. Be firm with the patient and do not let him persuade you that the condition is only a minor or temporary problem. Recognize the signs and symptoms and treat the patient aggressively. This will, potentially, save the patient’s life.

Use the following as general guidelines for those patients who have denied the seriousness of their condition and have waited to contact the EMS crew. These patients must be treated as a cardiac compromise and acute coronary syndrome patient and transported immediately:

- A patient who has a history of angina (steady chest discomfort that is brought on by activity, exercise, or stress, and usually lasts 2–15 minutes) who is having chest discomfort at rest that lasts longer than 20 minutes
- Recent onset of angina that progressively worsens
- Nocturnal angina (patient who is awakened by the pain at night)
- Angina unrelieved by rest or three nitroglycerin tablets over 10 minutes
- Chest discomfort that lasts greater than 5–10 minutes after rest

Keep in mind that, in some patients, the presentation of an acute coronary syndrome, such as a heart attack, may not follow a typical pattern of signs or symptoms (Figure 17-17). These are considered atypical presentations. The elderly, diabetics, and women often have atypical presentations when suffering a heart attack. These patients may only feel weak or short of breath or light-headed, and they will not present with chest discomfort or pain. Some patients, both men and women, suffer a “silent” heart attack, where there are no signs or symptoms that are truly recognizable. Also, the patient may not “look bad” in your general impression. He may appear to be relatively well aside from the chest discomfort or other complaints. The patient may present with one, two, or three of the symptoms. He does not have to have all of the symptoms to be categorized as an acute coronary syndrome or heart attack. One patient may present with only one symptom, whereas the next patient may have five symptoms. As always, err to benefit the patient and treat and transport expeditiously.

**Physical Exam and Baseline Vital Signs.** You will perform a physical exam on the responsive patient suffering from a possible acute coronary syndrome such as chest discomfort or breathing difficulty. During the exam, assess the following:

- **Pupils.** Sluggish or dilated pupils may suggest hypoxia and poor perfusion.
- **Oral cavity.** Cyanotic mucous membranes indicate hypoxia.
- **Neck.** Congestive heart failure or cardiac tamponade (fluid in the sac surrounding the heart) may produce jugular venous distention.
- **Chest.** Auscultate for abnormal breath sounds, especially crackles, which may indicate fluid in the alveoli from left ventricular heart failure.
EARLY SIGNS OF ACUTE CORONARY SYNDROME (HEART ATTACK)

- **Lower and upper extremities.** Assess for peripheral edema, suggesting heart failure, and peripheral cyanosis, usually indicating vessel disease.
- **Posterior body.** Presacral edema to the lower back is another indicator of heart failure that may be more prominent in the patient who is sedentary and commonly in a supine or lying position.

In addition to performing the focused physical exam, obtain and record the patient’s vital signs.

**Signs and Symptoms.** Signs and symptoms associated with cardiac compromise or acute coronary syndrome may vary widely. However, the most common are these:

- Chest discomfort or pain that radiates to any of the following areas: chest, neck, jaw, arm, or back; also epigastric (upper abdomen) pain that may be described as indigestion. (Review Figure 17-17.)
- Sudden onset of sweating (This may be a significant finding by itself.)

- Cool, pale skin
- Difficulty in breathing (dyspnea)
- Light-headedness or dizziness
- Anxiety or irritability
- Feelings of impending doom
- Abnormal or irregular pulse rate
- Abnormal blood pressure
- Nausea and/or vomiting

**ASSESSMENT TIPS**

Increased respiratory rate and heart rates in the acute coronary syndrome patient may indicate hypoxia or may be only a response to the chest pain or discomfort.

**Emergency Medical Care**

The American Heart Association Guidelines of 2010 emphasize the need to quickly recognize cardiac arrest and immediately begin chest compressions. Thus, the
arteries reoccluding and has antiplatelet effects. (See Figure 17-19 for the criteria and techniques for the administration of aspirin.)

6. Call for ALS backup; initiate early transport.

Reassessment

Although not all patients with chest pain/discomfort or cardiac compromise will deteriorate into cardiac arrest, be ready for this possibility. Closely reassess the breathing and pulse as you perform reassessment during transport. Be prepared to perform CPR and, as appropriate, use automated external defibrillation (as described in Chapter 15, “Shock and Resuscitation”) in the event that cardiac arrest does occur.

Summary: Assessment and Care

To review assessment findings that may be associated with cardiac compromise and emergency care for cardiac compromise, see Figure 17-20a, 17-20b, and 17-21.
Drug Profile
Aspirin

Medication Name
Aspirin is the generic name. This is the same aspirin that is purchased over the counter. Trade names of aspirin include:
- ASA
- Bayer
- Ecotrin
- St. Joseph’s
- Bufferin

Indications
All of the following criteria must be met before an EMT administers aspirin to a patient:
- The patient exhibits chest discomfort that is suggestive of a heart attack.
- The EMT has received approval from medical direction, whether on-line or off-line, to administer the medication.

Contraindications
Aspirin should not be given to a patient who is known to be allergic (hypersensitive) to the drug.

Medication Form
Tablet.

Dosage
The dosage of aspirin is 160–325 mg as soon as possible after the onset of the chest discomfort and symptoms of heart attack. It is recommended that 160–325 mg of a nonenteric aspirin be chewed and swallowed.

Administration
To administer aspirin:
1. Complete the history and physical exam of the cardiac patient and determine that the patient is suffering from an acute coronary syndrome that is suggestive of a heart attack.
2. Obtain approval from medical direction, either on-line or off-line, to administer the aspirin.
3. Be sure that the patient is alert and oriented.
4. Have the patient chew a 160–325 mg nonenteric tablet.
5. Reassess the patient and record the vital signs.

Actions
Aspirin (acetylsalicylic acid [ASA]) is a medication that produces a rapid antiplatelet effect. This effect decreases the ability of platelets to clump together during the clotting cascade and reduces the formation of a clot in the coronary artery at the site of the blockage. The medication also reduces the incidence of coronary reocclusion and recurrent ischemic event following in-hospital therapy with fibrinolytic agents. The aspirin is not used in this situation for its analgesic (pain relief) effects, and should be the nonenteric (not coated) type.

Side Effects
When used in this situation, aspirin has very few side effects. The patient may experience stomach irritation or heartburn, nausea, or vomiting. Although typically not used in the prehospital setting, there are aspirin suppositories (300 mg each) that are considered safe and effective for patients with severe nausea, vomiting, or a history of upper gastrointestinal tract disorders.

Reassessment
When you administer aspirin to a patient, you should conduct a reassessment. The aspirin is used in this situation not as a pain reliever but as a drug to prevent platelets from continuing to clump together and occlude the artery. Thus, there may not be an immediate relief in pain such as occurs with nitroglycerin. Be sure to record any changes in the patient’s condition and the reassessment findings.
### Assessment Summary

**CARDIAC COMPROMISE AND ACUTE CORONARY SYNDROMES**

The following findings may be associated with cardiac compromise and acute coronary syndromes.

### Scene Size-up

Look for evidence of:
- Home or portable oxygen tanks or concentrators indicating chronic respiratory problems

### Primary Assessment

**General Impression**
- Position of patient: tripod (may indicate pulmonary edema)
- Patient may have look of impending doom.
- Patient may be clutching chest.

**Mental Status**
- Alert to unresponsiveness
- Restlessness
- Agitation and irritability
- Anxiety

**Airway**
- Possibly occluded in patient with altered mental status

**Breathing**
- Signs of inadequacy or difficulty in breathing
- Abnormal sounds may be heard on auscultation (indicating heart failure)

**Circulation**
- Tachycardia or bradycardia
- Irregular
- Weak peripheral pulses
- Cyanosis to mucous membranes, around nose and mouth, nail beds, chest, neck
- Pale, cool skin

**Status: Priority Determination**

### Secondary Assessment

**History**
- Signs and symptoms:
  - Discomfort or pressure sensation in middle of chest that may radiate to neck, to jaw, down arms, or to the back
  - Difficulty in breathing
  - Light-headedness or dizziness
  - Anxiety and irritability
  - Nausea and vomiting
  - Known allergies to medication or other substances
  - Medications for cardiac conditions:
    - Prescribed nitroglycerin
    - Pre-existing cardiac disease
    - Hospitalized for cardiac condition
    - History of past heart attack

**Physical Exam**

**Head, neck, and face:**
- Cyanosis to face, neck, and mucous membranes
- Jugular venous distention (may indicate heart failure or cardiac tamponade)
- Nasal flaring
- Pupils sluggish to respond to light

**Chest:**
- Inspect for scars indicating previous cardiac surgery
- Retractions
- Breath sounds

**Abdomen:**
- Use of abdominal muscles when breathing

**Extremities:**
- Cyanosis to fingers and nail beds
- Pale skin
- Diaphoresis
- Peripheral edema

**Other Signs and Symptoms:**
- Nausea and vomiting
- Light-headedness or dizziness
- Sense of impending doom

**Baseline Vital Signs**
- BP: normal, high, or low
- HR: normal, tachycardia, bradycardia, irregular
- RR: increased
- Skin: pale and cool, diaphoresis, maybe cyanosis
- Pupils: dilated, sluggish to respond to light
- \( \text{SpO}_2 \): readings: may be normal or <95%

![FIGURE 17-20a](assessmentsummary_cardiaccompromiseacute coronarysyndromes.png) Assessment summary: cardiac compromise and acute coronary syndromes.
Emergency Care Protocol

CARDIAC COMPROMISE AND ACUTE CORONARY SYNDROMES

1. Establish and maintain an open airway.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. Apply pulse oximeter and monitor the SpO₂
5. According to the AHA 2010 guidelines, if the SpO₂ reading is less than 94%, the patient complains of dyspnea, or signs and symptoms of hypoxia, heart failure, or shock are present, administer oxygen by nasal cannula at 2 to 4 lpm. High concentration oxygen is no longer considered routine unless severe signs of hypoxia are present. Always follow your local protocol.
6. Place the patient in position of comfort (sitting or lying).
7. If the patient has signs and symptoms typical of cardiac-type chest discomfort and has prescribed nitroglycerin:
   • Nitroglycerin is a vasodilator and will reduce work-load of the heart, dilate coronary arteries, and supply more oxygen to the heart.
   Note: DO NOT ADMINISTER NITROGLYCERIN IF:
   Systolic BP is less than 90 mmHg or greater than 30 mmHg lower than the baseline systolic blood pressure.
8. Administer 160–325 mg of aspirin (according to local protocol).
9. Consider advanced life support.
11. Perform a reassessment of the patient every 5 minutes.

The heart rate is less than 50 bpm or greater than 100 bpm.
The patient has a suspected head injury.
The patient has already taken three doses.
The patient has taken tadalafil (Cialis), vardenafil (Levitra), or sildenafil (Viagra) within 48 hours (consult medical direction).
• Obtain an order from medical direction.
• Be sure the prescription is the patient’s.
• Wear gloves when touching nitroglycerin.
• Remove the nonrebreather mask from the patient.
• Have the patient lift his tongue.
• Place nitroglycerin tablet or spray under the tongue.
• Instruct the patient not to swallow.
• Replace the nonrebreather mask on the patient.
• Record time and reassess the patient.
• Side effects:
  Headache
  Decrease in blood pressure
  Changes in heart rate

FIGURE 17-20b Emergency care protocol: cardiac compromise and acute coronary syndromes.
Mechanism of injury present?

- Yes
  - Consider manual in-line stabilization
  - Open wound to chest?
    - Yes
      - Occlude with nonporous dressing
      - Assess mental status
      - Alert and able to obey commands
    - No
      - Assess mental status

- No
  - Airway open?
    - Yes
      - Suction if necessary
      - Head-tilt, chin-lift or jaw thrust
      - Oro- or nasopharyngeal airway
    - No
      - Assess breathing
      - Adequate
        - Administer oxygen if needed
      - Inadequate
        - PPV with O₂

Assess circulation
- Prescribed nitroglycerin?
  - Yes
    - Systolic BP >90 mmHg or not more than 30 mmHg below baseline systolic BP?
      - Yes
        - No suspected head injury?
          - Yes
            - Less than 3 doses taken by patient?
              - Yes
                - Adult patient?
                  - Yes
                    - Administer nitroglycerin
                  - No
                    - Relieve of pain?
                      - Yes
                        - Systolic BP >90 mmHg or not more than 30 mmHg below baseline systolic BP?
                          - Yes
                            - Consider redose of nitroglycerin every 3–5 minutes up to a total of 3 doses
                          - No
                            - Transport
                      - No
                        - Consider re-dosing of nitroglycerin every 3–5 minutes up to a total of 3 doses
            - No
              - Adult patient?
                - Yes
                  - Administer nitroglycerin
                - No
                  - Reassessment
        - No
          - Consider administering 160 to 325 mg aspirin
          - Assess mental status
          - Alert and able to obey commands
          - Assess mental status
      - No
        - Assess mental status

- No
  - Airway open?
    - Yes
      - Suction if necessary
      - Head-tilt, chin-lift or jaw thrust
      - Oro- or nasopharyngeal airway
    - No
      - Assess breathing
      - Adequate
        - Administer oxygen if needed
      - Inadequate
        - PPV with O₂

Rapid secondary assessment

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

FIGURE 17-21 Emergency care algorithm: cardiac compromise.
EMT SKILLS 17-1

Assisting a Patient with Prescribed Nitroglycerin

17-1A Have the patient sit or lie down. Assess blood pressure. Systolic pressure must be greater than 90 mmHg.

17-1B Obtain an order from medical direction to administer the nitroglycerin.

17-1C Check the medication to ensure that it is prescribed to the patient, it is the proper medication, and it has not expired.

17-1D Place the nitroglycerin tablet under the patient’s tongue.
Patients suffering from an acute coronary event may be among the most challenging patients encountered by the EMT. They may present anywhere on the continuum from being alert and oriented with only minimal symptoms to being unresponsive and just moments from cardiac arrest. Compounding this picture is that the cardiac patient may go from one extreme to the other very quickly, without much warning for the EMT. Therefore, the EMT must always maintain a high degree of suspicion with cardiac patients that they may deteriorate into cardiac arrest very suddenly.

Treatment for cardiac-related chest pain and other coronary emergencies must be delivered in a timely manner, without error. Patient outcomes are always better if they do not degrade into cardiac arrest. If they should arrest, outcomes are generally poor, carrying with them a low rate of successful resuscitation. To increase the survival rate should your patient be in cardiac arrest on your arrival (or arrest in your presence), always remember the components of the Chain of Survival as discussed in Chapter 15. Immediate recognition and activation of EMS, early CPR, rapid defibrillation, effective advanced life support, and integrated post-cardiac-arrest care are all necessary if rates of patient survival from cardiac arrest are going to improve.

When caring for a patient in cardiac arrest, always do your best in each of the interventions you provide. Remember to “push hard and put fast” with compressions so that the brain and heart can still receive blood flow during the arrest management. Ensure adequate ventilations and provide oxygen during the arrest as well. The automated external defibrillator should be utilized specifically as addressed earlier in the chapter so that those patients in ventricular fibrillation will have the greatest opportunity for survival. Patients in nonventricular fibrillation cardiac arrest (identified by a “no shock” message on the AED) should also receive this high level of care so that they too may have the greatest chance for survival.

The patient near cardiac arrest, in cardiac arrest, or just coming out of cardiac arrest is probably one of the most challenging and dynamic situations the EMT will ever encounter. It requires a thorough understanding of the body, application of multiple skills simultaneously, and coordination of multiple EMS providers—all done in the shortest time possible so that the patient can be transported to the hospital for definitive care.
Case Study Follow-up

Scene Size-up
You have been dispatched to a 49-year-old male patient complaining of chest pain while eating dinner at a local restaurant. You don your gloves and grab the jump kit and oxygen as you leave the vehicle. You approach the patient and notice a moderately crowded dining room with several people around one particular table. There do not appear to be any hazards to your safety. You determine that there is only one patient. Upon arrival at the table you introduce your partner and yourself to the patient, who gives his name as Paul Antak.

Primary Assessment
After introducing yourself, you note that the patient is clutching his chest and ask, “What seems to be the problem, Mr. Antak?” The patient states, “I feel like someone is standing on my chest.” The patient is responsive, alert, and oriented. His airway is open and his breathing is rapid but adequate. His SpO2 is 91% on room air. Your partner initiates oxygen at 2 lpm by nasal cannula. The patient’s pulse is palpable. His skin is pale, cool, and slightly moist. There are no obvious signs of any injuries or other problems. You direct your partner to get the stretcher while you continue with the secondary assessment.

Secondary Assessment
You begin the history using the OPQRST format to assess Mr. Antak’s chest discomfort. Mr. Antak describes his discomfort as sudden in onset about 20 minutes ago. Nothing has made it better or worse. At first, he thought it was indigestion, but it did not go away. He describes it as a dull, squeezing pain that radiates to his left arm. He rates this as an 8 on a 1-to-10 scale of pain.

You obtain the rest of the history. His signs and symptoms are chest discomfort with some radiation to the left arm, an extremely irregular pulse, and sweaty pale skin. He has no known allergies. He does take medication for high blood pressure, and his physician gave him nitroglycerin to take in case of severe chest discomfort. Mr. Antak states that, although he has the nitroglycerin with him, he has not taken any yet. There is no past medical history other than the high blood pressure. He was in the middle of his meal. There were no similar events prior to this incident.

Your physical exam reveals pupils that are equal and responsive to light, but slightly sluggish. The oral mucosa is normal in color. The jugular veins are normal. The breath sounds are equal and clear bilaterally. The abdomen is soft, not tender, and not distended. The pulses are present in all extremities. There is no edema to the feet, ankles, hands, or sacral area. You assess Mr. Antak’s baseline vital signs: radial pulse—irregular rate of 98; blood pressure—180/110 mmHg; breathing—28 per minute; skin—cool and moist. The SpO2 reading is maintained at 95% while he is on the nasal cannula at 2 lpm.

You contact your base hospital for medical direction’s approval to assist in administration of nitroglycerin and aspirin. This is granted by Dr. Settler. You ask Mr. Antak for his medication container and note that it contains sublingual nitroglycerin, prescribed for him, with an expiration date of 1 year from today’s date. Mr. Antak says he has never taken nitroglycerin before, so you explain that he may get a headache or become light-headed from the medication. You explain that he will need to keep the tablet under his tongue and not swallow until it has dissolved completely. You ask the patient to lift his tongue and when he does, you place one tablet under the tongue. Once the nitroglycerin is dissolved, you then administer 160 mg of chewable aspirin and ask the patient to chew the tablet.

While you are preparing to move Mr. Antak from his chair to the stretcher, he tells you that he is suddenly feeling worse. You verbally reassure him; however, he suddenly loses consciousness and has a seizure that lasts about 5 seconds. You assess him for a verbal response and find none. Your partner simultaneously checks for a pulse and breathing and also finds none. Your patient is now in cardiac arrest. You and your partner then move him carefully to the floor, and your partner immediately initiates chest compressions as you apply the AED. During this brief time of rhythm analysis, you call dispatch on your portable radio to obtain an estimated time of arrival of the backup ALS unit.

The AED indicates a shockable rhythm and begins to charge up for the defibrillation attempt. After ensuring that you, your partner, and all bystanders are clear from the patient, you depress the “shock” button on the AED. You note some muscular contraction to the chest wall with the defibrillation. Immediately after the shock delivery, you resume CPR with chest compressions for five cycles of 30 compressions and 2 ventilations. Following this 2-minute period of CPR, you stop to reassess the breathing and pulse and find a palpable carotid and radial pulse; however, the patient is still unresponsive and is not yet breathing. You continue to ventilate Mr. Antak once every 6 seconds. The ALS providers arrive on scene and ask, “Where are you at with your cardiac arrest management?”

Reassessment
By the time the ALS crew has provided advanced airway management, intravenous access, and some medication administration, you are en route to the hospital. Your partner is driving the ambulance and one of the ALS providers is in the back with you. On the way to the hospital you constantly ensure that the pulse is present, the airway device is inserted properly, and the oxygen is always flowing. The pulse oximetry currently reads 98%, and you notice that the patient is starting to display some random extremity movement. The blood pressure is currently 102/84 mmHg, the heart rate is 102 and still irregular, and you are ventilating the patient at 10 times per minute with a bag-valve-mask device connected to supplemental oxygen. You radio the hospital with an update on Mr. Antak’s condition and your estimated time of arrival.

Follow-up

An author podcast is available by going to www.bradybooks.com, Author Podcasts.
IN REVIEW

1. Define the cardiovascular system.
2. Explain the exchange that takes place between the capillaries and the body’s cells.
3. Define perfusion and shock (hypoperfusion).
4. Name the common signs and symptoms of cardiac compromise.
5. Describe the standard emergency medical treatment for patients with signs and symptoms of cardiac compromise.
6. Explain the dosage of aspirin in a cardiac emergency and how it is administered.
7. Explain under what conditions the administration of nitroglycerin is indicated.

CRITICAL THINKING

You arrive on the scene and find a 59-year-old male patient complaining of chest discomfort and shortness of breath. The patient has assumed a tripod position while sitting at the edge of his bed. You notice that he has four pillows on the side of the bed where he sleeps. His complexion appears to be ashen gray and he is extremely diaphoretic. His breathing is very labored, and he speaks two to three words followed by a gasp for a breath. His radial pulse is present and his skin is extremely cool and clammy. His heart rate is 134 bpm, blood pressure is 178/100 mmHg, and respirations are 32 per minute and labored. His SpO2 reading is 72%. He has a history of three previous myocardial infarctions. He has crackles in the lower and middle lobes of both lungs. His hands and ankles are swollen.

1. What emergency care would you provide during the primary assessment?
2. What condition do you suspect the patient is experiencing?
3. What medication may improve the patient’s condition?
4. How would you move the patient from the second-floor bedroom to the ambulance stretcher on the first floor?
5. In what position would you transport the patient?
6. What oxygen device would you apply and at what liter flow?
7. What is causing the crackles in the lungs?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD •** Medicine (Content Area: Neurology)

**COMPETENCY •** Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES •** After reading this chapter, you should be able to:

18-1. Define key terms introduced in this chapter.
18-2. List possible structural, toxic-metabolic, and other causes of altered mental status.
18-4. Explain the reason for paying particular attention to airway assessment and management in patients with altered mental status.
18-5. List signs and symptoms of altered mental status commonly associated with:
   a. Trauma
   b. Nontraumatic or medical conditions
18-6. Determine the need for the following interventions in patients with altered mental status:
   a. Manual spinal stabilization
   b. Opening and maintaining the airway
   c. Oxygenation
   d. Ventilation
   e. Positioning
   f. Transport
18-7. Explain the responsibilities of the general public and EMS in the care for a stroke patient that are identified by the American Heart Association as “Detection,” “Dispatch,” and “Delivery.”
18-8. Describe the pathophysiology of stroke and distinguish between ischemic strokes and hemorrhagic strokes.
18-9. Describe the relationship between stroke and transient ischemic attack.
18-10. Describe an assessment-based approach to stroke and transient ischemic attack.
18-11. Discuss the use of the Cincinnati Prehospital Stroke Scale and the Los Angeles Prehospital Stroke Screen.
18-12. Discuss the role of blood glucose determination in the assessment of patients with altered mental status and neurological deficits.
18-13. Describe ways of communicating with patients who have difficulty speaking.
18-14. Recognize indications that a headache may have a potentially life-threatening underlying cause, such as toxic exposure, hypertension, infectious disease, or hemorrhagic stroke.
18-15. Describe the appropriate emergency medical care for a patient suffering from headache.

**KEY TERMS •** Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- altered mental status p. 525
- coma p. 525
- embolic stroke p. 529
- hemorrhagic stroke p. 529
- ischemic stroke p. 529
- neurological deficit p. 528
- nontraumatic brain injury p. 528
- reticular activating system (RAS) p. 525
- stroke p. 528
- thrombotic stroke p. 529
- transient ischemic attack (TIA) p. 532
It is important for the EMT to recognize that a patient may be having a stroke, provide emergency care, begin rapid transport, and notify the receiving medical facility that the patient is possibly suffering a stroke. Stroke can lead to a compromised airway and inadequate breathing. Early recognition and expeditious transport are vital. You must continuously monitor the airway and breathing and be prepared to intervene.

Headache may be a symptom of an underlying condition or may be a condition in itself. You should consider headache a serious symptom and conduct an assessment looking for an underlying condition as its cause.

**INTRODUCTION**

In order for a patient to remain in an awake or conscious state, two functioning components are necessary: an intact reticular activating system and at least one cerebral hemisphere. The reticular activating system (RAS) is not an actual structure but a network of nerve cells in the brainstem that constantly transmit environmental and sensory stimuli to and from the cerebrum. If this network is damaged or becomes dysfunctional, the patient will lose consciousness. Similarly, if both cerebral hemispheres are damaged or become dysfunctional, the patient will no longer remain conscious. Thus, in order for the patient to remain in an awake and alert state, the reticular activating system and at least one cerebral hemisphere must be intact.

An altered mental status is a significant indication of injury or illness in a patient. The alteration may range from simple disorientation to complete unconsciousness in which the patient is not responsive, even to painful stimuli. An unconscious state in which the patient does not respond to painful stimuli is referred to as coma. A change in the patient’s mental status is an indication that the central nervous system has been affected in some manner. Causes may include trauma, where the brain is injured from a blunt force or penetrating object, or nontraumatic causes such as alterations in the patient's blood sugar level or blood oxygen level.

The cause of an alteration in mental status usually falls into one of two categories: structural or toxic-metabolic. A structural cause of altered mental status results from a space-occupying lesion or depression or from destruction of brain tissue.

### Structural Causes of Altered Mental Status
- **Brain tumor**
- **Hemorrhage in the cranium but outside of the brain**
- **Hemorrhage in the brain tissue**
- **Direct brain tissue damage from trauma to the brain**
- **Degenerative disease of the brain**
- **Brain abscess or infection**

Toxic-metabolic causes, as implied by the name, result from circulating toxins or metabolites or from the lack of necessary metabolic substances such as glucose and oxygen.

### Toxic-Metabolic Causes of Altered Mental Status
- **Severe hypoxia or anoxia** (reduced oxygen or no oxygen)
- **Abnormal blood glucose conditions** (high blood glucose or low blood glucose)
- **Liver failure**
- **Kidney failure**
- **Poisoning** (e.g., carbon monoxide, cyanide)

There are many other causes of altered mental status that are difficult to fit into one of the categories just listed. These causes may be related to a condition involving drugs, the cardiovascular system, the respiratory system, or infection.

### Other Causes of Altered Mental Status
- **Shock**
- **Drugs that depress the central nervous system** (e.g., narcotics, alcohol)

---

**Case Study**

**The Dispatch**

EMS Unit 102—respond to 48 Delason Avenue—you have a 73-year-old female patient who has slurred speech and is unable to move her right arm or leg. Time out is 0840 hours.

**Upon Arrival**

Upon your arrival you find an elderly woman, who is not alert, lying in bed. Her husband tells you that when she woke up she was “talking funny and slurring her words.”

Also, he noticed that she was unable to move her right hand, arm, leg, or foot. You also note the smell of urine and feces.

How would you proceed to assess and care for this patient?

During this chapter, you will learn about assessment and emergency care for a patient suffering from an altered mental status, stroke, or headache. Later, we will return to the case and apply the procedures learned.
Post seizure (the patient has suffered a seizure and is just beginning to recover)
- Infection
- Cardiac rhythm disturbance
- Stroke

In any patient with an altered mental status, it is vital that you manage any life-threatening injuries or conditions, recognize the mental status change, document it, and continue to monitor the patient for further deterioration.

Assessment-Based Approach: Altered Mental Status

Scene Size-up

Do a scene size-up to begin to find out why the patient has an altered mental status. Based on the dispatch information and a scan of the scene, determine if the patient has been injured or is suffering from a medical illness. For example, if you arrive on the scene and find an extension ladder next to the house and the patient lying near it, you would immediately expect that the patient has suffered some type of injury from a fall. As you are approaching the patient, inspect the scene for a mechanism of injury that would be significant enough to cause an alteration in mental status. This information may also be gathered from your dispatch information, the patient, relatives, or any bystanders at the scene.

If no mechanism of injury is apparent, you would then suspect that the altered mental status is the result of a medical illness. As you are approaching the patient, look for clues that may indicate the nature of the illness. Alcohol bottles, drug paraphernalia, home oxygen tanks, or chemicals may help explain the cause.

The patient’s medications may provide the most valuable information. Have a family member gather the patient’s medications while you are performing your assessment. If no family members are present, ask an Emergency Medical Responder or police officer at the scene to look near the kitchen and bathroom sink, kitchen table, and nightstand for both prescription and nonprescription medications. Since insulin, the medication taken to control the blood sugar in diabetes, must be refrigerated, be sure to instruct the individual to look inside the refrigerator. Once the medications have been gathered, they should be kept with the patient. This may provide the emergency department with vital information that would otherwise not be readily available.

If more than one patient at the scene presents with altered mental status, suspect that some type of hazardous gas or poison may be causing the illness. Note any unusual odors. The first priority is to protect yourself so you don’t become a patient also. The second priority is to move the patient out of the hazardous environment. If you do not have the proper equipment and training, call for experts to bring the patient out of the danger zone.

Primary Assessment

Stabilize the spine if injury is possible. Pay particular attention to the patient’s airway and breathing. Severe alterations in mental status may cause the patient to lose his ability to maintain his own airway. The jaw and tongue become relaxed, fall back, and block the airway. An unresponsive patient commonly has no gag or cough reflex and therefore is unable to keep his airway clear of secretions, blood, and vomitus.

ASSESSMENT TIPS

Even though the patient may still have a gag or cough reflex, he may not be able to maintain his own airway if he has an altered mental status.

The breathing rate and depth may be inadequate, so be prepared to perform positive pressure ventilation. Because hypoxia is a cause of altered mental status, patients with an altered mental status should initially receive supplemental oxygen therapy. If the SpO2 is ≥94% and if no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen once the cause of the altered mental status is determined. If the SpO2 is ≤94% or if signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used. It is also important to recognize that the poor breathing status or blocked airway may be the cause of the altered mental status as well as the result.

Secondary Assessment

Your partner may take baseline vital signs as you begin gathering information from the patient, relatives, or bystanders regarding the patient’s history. It is best to use the patient as the main historian. However, if the patient is disoriented or suffering a severely depressed mental status, he may be unable to provide the necessary answers.

History. During your history, ask the following questions:

- What were the signs and symptoms the patient was complaining of prior to the alteration in the mental status?
- Did the signs and symptoms seem to get progressively worse or better?
- Does the patient have any known allergies?
- What medications, prescription and nonprescription, is the patient taking?
- What is the patient’s past medical history? When was the last time he has seen a doctor for his medical condition?
- When did the patient last have something to eat or drink? What did he eat or drink? Did he take any drugs or ingest any alcohol?
• What was the patient doing prior to the onset of the altered mental status?
• Was the onset of signs and symptoms gradual or sudden?
• Did the patient suffer from a seizure, severe headache, or confusion prior to the alteration in the mental status?
• How long has the patient been sick or suffering from these signs and symptoms? When was the patient last well?

If the patient is responsive enough to provide accurate information, collect the history first, followed by the physical examination. Finally, obtain a set of baseline vital signs. If more than one EMT is on the scene, the physical exam can be conducted and baseline vital signs can be obtained by one EMT as the other EMT collects the history. If the patient is unresponsive or is unable to answer history questions appropriately, move directly to the physical examination, collect the baseline vital signs, and then collect the history from any relatives or bystanders at the scene.

**Physical Exam.** The physical exam conducted on a patient with an altered mental status must include examination of the following:

- **Head** for any evidence of possible trauma
- **Pupils** for indications of a head injury (unequal or fixed), drugs (narcotics usually cause pinpoint pupils), hypoxia (sluggish to respond to light)
- **Mouth and oral mucosa** for cyanosis and pallor indicating hypoxia and poor perfusion
- **Chest** for indication of any trauma leading to hypoxia from lung dysfunction
- **Breath sounds** indicating poor gas exchange from injury (pneumothorax) or abnormal breath sounds indicating a possible pulmonary or cardiac condition, for example, crackles (pulmonary edema) or wheezing (asthma attack)
- **Abdomen** for any evidence of intraabdominal bleeding such as a rigid and tender abdomen (look at the patient’s face when palpating the abdomen for grimacing from pain)
- **Lower and upper extremities** for motor and sensory function and pulses
- **Lower extremities** for peripheral edema (may indicate congestive heart failure)
- **Posterior body** for sacral edema (may indicate congestive heart failure)

**ASSESSMENT TIPS**

Narcotics like morphine, heroin, and codeine will typically cause the pupils to constrict and become pinpoint in size. However, the narcotics meperidine (Demerol), propoxyphene (Darvon), pentazocine (Talwin), and some others may not cause the typical constriction of the pupils.

The vital signs may also provide clues to the cause of the altered mental status. For example, an extremely rapid heart rate or a very slow heart rate may cause a state of poor perfusion to the brain and lead to an altered mental status. A low blood pressure or an extremely high blood pressure may also provide clues. Altered mental status may result from poor perfusion in a patient with a low blood pressure, whereas a high blood pressure may be associated with a stroke that is causing the altered mental status. A low pulse oximeter reading may indicate an altered mental status resulting from hypoxia. If a blood glucose monitor (commonly referred to as a glucometer in EMS) is available, check the patient’s blood sugar level to determine if a low blood sugar level may be the cause of the altered mental status. (Checking the blood glucose level using a blood glucose monitor will be covered in more detail in Chapter 20, “Acute Diabetic Emergencies.”)

**Signs and Symptoms.** The signs and symptoms associated with an altered mental status will vary depending on the cause, whether from trauma or from a medical cause.

**Signs and Symptoms of Altered Mental Status Commonly Associated with Trauma**

- Obvious signs of trauma: deformity, contusions, abrasions, punctures or penetrations, burns, tenderness, lacerations, or swelling
- Abnormal respiratory pattern
- Increased or decreased heart rate
- Unequal pupils
- High or low blood pressure
- Discoloration around the eyes (late sign)
- Discoloration behind the ears (late sign)
- Pale, cool, moist skin
- Flexion (decorticate posturing—arms flexed, legs extended) or extension (decerebrate posturing—arms and legs extended)

**Signs and Symptoms of Altered Mental Status Commonly Associated with a Nontraumatic or Medical Condition**

- Abnormal respiratory pattern
- Dry or moist skin
- Cool or hot skin
- Pinpoint, midsize, dilated, or unequal pupils
- Stiff neck
- Lacerations to the tongue indicating seizure activity
- High systolic blood pressure and low heart rate
- Loss of bowel or bladder control
- Abnormally high or abnormally low blood glucose reading

**Emergency Medical Care**

If assessment has revealed an injury or set of medical signs and symptoms, perform the appropriate emergency medical care for those specific injuries or medical conditions. In addition, if the patient displays an altered mental status, provide the following care:

1. **Maintain manual spinal stabilization** if trauma is suspected.
2. Maintain a patent airway. A patient with an altered mental status may not be able to maintain his own airway. If this is the case, insert a nasopharyngeal or oropharyngeal airway adjunct to help keep the patient’s airway open.

3. Suction any secretions, vomitus, or blood. Closely monitor the airway by frequently inspecting inside the mouth and suctioning any secretions, blood, or vomitus.

4. Maintain adequate oxygenation. It is extremely important that the patient continuously receive a concentration of oxygen to maintain his SpO2 reading at or above 94% and to eliminate any signs of hypoxia. If the patient becomes alert and oriented and the SpO2 is ≥94% and if no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. If the SpO2 is ≤94% or if signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula to maintain an SpO2 reading of ≥94%. If signs of severe hypoxia are present, a nonrebreather mask at 15 lpm could be used. A sign of severe hypoxia may be an altered mental status; thus, it may be prudent to maintain oxygen administration via a nonrebreather mask at 15 lpm. If the ventilations are being assisted, make sure the device used to ventilate the patient is properly connected to oxygen.

5. Be prepared to assist ventilation. Continuously assess the breathing status. If the breathing rate or depth becomes inadequate, immediately begin positive pressure ventilation with supplemental oxygen connected to the ventilation device.

6. Position the patient. Patients with an altered mental status should be placed in a lateral recumbent (recovery) position to avoid possible aspiration. If spinal injury is suspected, the patient must be fully immobilized on a long spine board. The spine board and patient may then be rotated as a unit to place the patient on his side if necessary to clear the airway. If the altered mental status patient requires ventilation, do not place him in a lateral recumbent position. It will not be possible to effectively establish and maintain an adequate mask seal and perform bag-valve-mask ventilation with the patient in a lateral position. Place the patient needing ventilation in a supine position and be sure to have suction readily available.

7. Transport. Any patient with an altered mental status must be transported to a medical facility for further evaluation. Consider ALS intercept according to local protocols.

Reassessment

Continuously monitor for changes in the patient’s mental status, airway, breathing, and circulation. Record the vital signs and communicate your findings to the receiving medical facility. For a patient with an altered mental status, repeat the reassessment every 5 minutes.

STROKE

Neurological Deficit Resulting from Stroke

The ability to be alert and aware of your surroundings, to speak, to feel sensations, and to move are all functions of the brain and nervous system. When the patient loses some or all of these abilities, he is experiencing a neurological deficit. A neurological deficit is defined as any deficiency in the functioning of the brain or nervous system. Altered mental status, slurred or absent speech, paralysis, weakness, and numbness are all signs and symptoms of neurological deficit.

A neurological deficit will alert you to the possibility of a condition that is affecting the patient’s central nervous system, which is composed of the brain and spinal cord. Thus, you must look for signs and symptoms of both traumatic and medical conditions that may be affecting the brain or the spinal cord. For instance, someone whose spinal cord or brain has been injured by a bullet and someone who has suffered a stroke may both lose the ability to feel sensation or the ability to move the arms or legs. In Chapter 31, “Head Trauma,” and Chapter 32, “Spinal Column and Spinal Cord Trauma,” you will learn how to assess and care for patients with head and spinal cord injuries caused by trauma (such as from a penetrating wound or a fall). In this chapter, we are primarily concerned with care for the patient with a nontraumatic brain injury, or a stroke, which is a medical injury to the brain that is not related to trauma.

Acute Stroke

According to the American Heart Association, the third leading cause of death in the adult population is stroke. Approximately 700,000 people each year will suffer a stroke for the first time, or a person with a history of a stroke will suffer another stroke. Of those patients, approximately 158,000 will die as a consequence of the stroke.

Time is a critical factor in the emergency care of stroke. Therefore, emergency medical services play a major role in the management of the stroke patient. One of the most significant factors that make a difference in the care and prognosis of the patient is early recognition of the stroke. Early recognition of a stroke leads to early transport and treatment in the emergency department.

Drugs and mechanical devices are now available that may be used on certain stroke patients to reduce or even reverse the consequences of the stroke by breaking up the clot causing the obstruction. These drugs must be administered within 3 hours from the first sign or symptom of the onset of the stroke. The patient must be delivered to the emergency department at least within 2 hours from the onset of the signs and symptoms of the stroke to allow the emergency department personnel enough time to collect the necessary information.
to make a decision whether to administer the drugs to destroy the clot causing the stroke. Other therapies to reverse stroke, typically available at specialized centers, can extend the window of opportunity to 6 hours.

**ASSESSMENT TIPS**

The time of onset of a stroke is commonly defined as the last time the patient was seen neurologically intact, meaning without any neurological deficit such as numbness, weakness, paralysis, slurred or stuttering speech, or cognitive problems.

For this reason, the patient or a relative or bystander must recognize signs and symptoms of a stroke and immediately call 911 or call the number to access the emergency medical services. Once emergency medical services arrive at the scene, they must also immediately recognize the signs and symptoms of stroke, assess the patient, provide initial emergency medical care, prepare the patient for rapid transport, and notify the receiving medical facility of transport of a possible stroke patient.

**PATHOPHYSIOLOGY PEARLS**

Atrial fibrillation, an irregularly irregular heart rhythm, is a common risk factor for stroke. The atrial fibrillation itself is not a lethal rhythm and is a common chronic rhythm disturbance in the elderly.

An embolic-type stroke occurs most often when the patient is awake and active. The onset of signs and symptoms is usually much more sudden than in a thrombotic stroke, and headache, seizure activity, or brief periods of unresponsiveness are more common.

**Types of Stroke**

A stroke is caused by interruption of blood flow to the brain. This occurs either by blockage of an artery that is carrying blood to a specific area within the brain or from bleeding within the brain resulting from a ruptured cerebral artery. The blockage is referred to as an ischemic stroke and the bleeding is referred to as a hemorrhagic stroke (Figures 18-1a and 18-1b).

**Ischemic Strokes**

Ischemic strokes occur when the cerebral artery is blocked by a clot or other foreign matter. A clot that develops at the site of occlusion is called a thrombus, and the process of clot formation is referred to as thrombosis. A stroke resulting from thrombus formation is called a thrombotic stroke. A clot or other matter that has traveled from another area of the body is called an embolus. When the embolus lodges in a cerebral artery and occludes it, it is known as a cerebral embolism and results in an embolic stroke.

**Thrombosis.** As the body ages, it is common for plaque deposits to form on the inner wall of arteries and cause them to narrow, reducing the amount of blood they can carry. This process is called atherosclerosis, and the narrowed portions of the arteries are common sites for blood clot formation. Hypertension can also wear away the smooth inner lining of the artery, leaving rough areas. These areas are likely to develop plaque and are also common sites for clot or thrombus formation. When a thrombus forms inside an artery, it can completely block the flow of blood through that artery to the brain. This results in the death of brain tissue, which is a stroke.

Because the narrowing and eventual occlusion of the artery occurs over a longer period of time than an embolic-type occlusion, the onset of signs and symptoms of a thrombotic-type stroke is much slower. This is the most common type of stroke. Severe headache is not a common symptom in a thrombotic stroke.

**Embolism.** In the stroke patient, an embolus usually originates from the carotid artery in the neck or from the heart. The clot travels until it becomes lodged in a small artery in the brain, blocking blood flow. The brain tissue beyond the point of blockage then begins to die from a lack of oxygen and nutrients. The embolus causing brain tissue death is most often made of clotted blood but may consist of air bubbles, tumor fragments, or fat particles.

**Hemorrhagic Strokes**

A hemorrhagic stroke results from the rupture of an artery that causes bleeding within the brain (intracerebral) or in the space around the outer surface of the brain (subarachnoid space). People with hypertension
(high blood pressure) are likely candidates for hemorrhagic stroke since ruptures are most likely to occur in arteries that have been damaged by hypertension. The constant high pressure wears away the inner surface of the artery and weakens it, leading to rupture and hemorrhage. An aneurysm, which is a weakened and dilated area within an artery wall, is a common cause of subarachnoid hemorrhages. The weakened area may be a congenital defect that has been present since birth. This is a common cause of strokes in younger, healthy adults.

The onset of signs and symptoms associated with a hemorrhagic stroke is usually very sudden and often occurs during physical activity. Headache is a common and often severe symptom. The patient commonly complains, “This is the worst headache I have ever had.” The patient frequently presents with an altered mental status that rapidly deteriorates. Seizures and stiff neck are also common. An atypical picture without mental deterioration is also possible. Hence, any patient with sudden onset of headache must be considered serious.

**PATHOPHYSIOLOGY PEARLS**

Chronic hypertension (HTN), which is high blood pressure, is a common risk factor for hemorrhagic strokes.

It is difficult to distinguish between the two types of stroke—ischemic and hemorrhagic—in the field, because they may present with similar signs and symptoms. However, it is extremely important to collect an accurate history and gather information in the physical exam to pass on to the emergency department, because the information may help the emergency department staff to determine which type of stroke it is. Distinguishing between the types of stroke is critical in the continued care of the patient. The primary difference is that the patient...
Brain tissues distal to a rupture, thrombus, or embolus receive little or no perfusion and become ischemic (starved of oxygen) and eventually infarcted (dead). When a thrombus grows slowly enough, collateral arteries may form parallel to the blocked artery to perfuse or partially perfuse the oxygen-starved area of the brain.

Suffering from an ischemic stroke can receive the drug, a fibrinolytic, to break up the clot and restore perfusion to the area of the brain that was not receiving an adequate supply of blood. A hemorrhagic stroke patient cannot receive a fibrinolytic drug because it may increase the amount of bleeding within the brain, worsen the stroke, and possibly lead to the patient’s death.

Your role as an EMT is to provide supportive care to the patient by managing any immediate life threats and by collecting the most accurate information possible to report to the emergency department. Your purpose in collecting the information is not to distinguish between the types of stroke but to report it accurately to the emergency department staff. The information you gather at the scene is critical to care of the patient in the emergency department.

Even though you, as an EMT, will not need to determine the type of stroke, it is still important to understand the different types and causes of stroke.

**Stroke or Transient Ischemic Attack**

**Stroke**

Strokes most often affect the elderly who have a history of atherosclerosis (fat deposits in the arteries), heart disease, or hypertension (high blood pressure). According to the American Heart Association Council on Stroke, the most likely candidate for stroke has high blood pressure and a history of brief, intermittent stroke like episodes called transient ischemic attacks (TIAs), which we will discuss in the next section.

The signs and symptoms of stroke are associated with the specific area of the brain that has been affected by a disruption in the blood flow. Most commonly, it involves the areas that control speech, sensation, and muscle function. The onset of the signs and symptoms is usually sudden and may be accompanied by a seizure, headache, or the inability to swallow (dysphagia). The patient may also experience difficulty in breathing (dyspnea).

Paralysis is a common sign in the stroke patient. Another common sign is facial droop, in which there is a loss of facial expression on one side and the facial features droop downward. Typically, the paralysis will affect one extremity (monoplegia) or both extremities on one side of the body (hemiplegia) (Figure 18-2). Because the nerves on one side of the brain cross over at the level of the medulla (at around the level of the upper lip) and control the movement and sensation on the other side of the body, the damage is usually noticeable on the side opposite the affected area. Therefore, if the stroke occurs on the left side of the brain, the damage is noticeable on the right side of the body; if the stroke occurs on the right side of the brain, the damage is evident on the left side of the body.

It is rare that paralysis from a stroke affects both extremities on both sides of the body. Usually, the face will be paralyzed on one side and the extremities will be weak or paralyzed on the opposite side. The pattern of paralysis is one factor that will help you distinguish stroke from a spinal injury, which, unlike stroke, will frequently cause paralysis to both legs (paraplegia) or to all four extremities (quadriplegia).
Some stroke patients experience only weakness in the arms and legs and not paralysis. Carefully monitor the patient because the weakness may progress to complete paralysis.

In stroke patients, alterations in mental status commonly range from alertness to simple confusion or dizziness to complete unresponsiveness. The speech of the patient may be slurred (dysphasia) or completely absent (aphasia). Stroke patients may also speak clearly, uttering nonsensical words (fluent or expressive aphasia). The patient may experience double or blurred vision, loss of vision in one eye, or loss of a visual field.

**Transient Ischemic Attack**

Patients who experience a transient ischemic attack (TIA) develop most of the same signs and symptoms as those who are experiencing a stroke. The key difference between a stroke and a TIA is that the signs and symptoms of a TIA disappear without any obvious permanent neurological deficits. According to the National Institute of Neurologic Disorders and Stroke (NINDS), the signs and symptoms of the TIA will typically resolve within 1 to 2 hours after the onset, however, it may last up to 24 hours. Ischemia, which refers to an oxygen deficit in the tissues, affects the brain and causes the strokelike signs and symptoms to appear. Reversal of the ischemia leads to disappearance of the strokelike signs and symptoms.

**PATHOPHYSIOLOGY PEARLS**

A TIA that lasts longer than 10 to 15 minutes may be a small stroke, not truly a TIA.

For example, you arrive on the scene and find a 70-year-old male patient who responds only to verbal stimuli, has right-sided facial droopiness, has slurred speech, and has paralysis to the right arm and leg. You assess the patient and begin your emergency care. By the time you have loaded the patient into the ambulance, 10 minutes have passed. The patient is now alert, able to move his right extremities, and speaking much more clearly, but he still complains of weakness to the right side of his body. When you arrive at the emergency department 13 minutes later, the patient has completely normal motor and sensory function in all extremities and is speaking without any difficulty. The patient has no apparent signs and complaints of nothing. In fact, clear documentation by the EMT of the symptoms that prompted the call to EMS may be the only reliable clue to the diagnosis.

This would be typical of a TIA. In contrast, the stroke patient’s signs and symptoms would have not disappeared and might have worsened. You should realize that the patient who is experiencing a TIA will be just as frightened as one who is experiencing a stroke. Maintain a reassuring, optimistic, and hopeful attitude in caring for patients with TIA.

TIAs are important to recognize and report. Although this incident is frightening for patients, some may refuse emergency care and transportation to a medical facility because the signs and symptoms disappear. However, almost a third of those who suffer a TIA will eventually have a stroke, and many of those patients will suffer the stroke within a month after the TIA. Therefore, you must encourage the patient to seek further examination and medical care.

The emergency care for the patient suffering a TIA is the same as that discussed later in the chapter for the patient who displays signs and symptoms of a stroke.

**Assessment-Based Approach: Stroke and Transient Ischemic Attack**

**Scene Size-up**

The dispatch information or someone on the scene may alert you to the patient’s neurological deficit or altered mental status: sudden weakness of the face, hand, arm, or leg; trouble speaking or stuttering; difficulty seeing in one or both eyes; problem walking or a loss of balance or coordination; confusion; dizziness; or a sudden onset of a severe headache. As you arrive, scan the scene to try to determine whether the neurological deficit is due to trauma or to a medical condition. Look for any signs that would make you suspect that the patient’s head or spine has been injured. Scan the scene for alcohol, drugs or drug paraphernalia, and prescription or illegal drugs, which are other possible causes of altered function. Specifically, look for evidence of amphetamines, cocaine, and other stimulants since they are related to nontraumatic brain injury in young adults.

Note where the patient is found and how he is dressed. Many strokes occur at night and the patient awakens with the neurological deficit. You would expect that a patient who is found in bed or wearing nightclothes is more likely to be suffering from a stroke than from a traumatic brain injury. Another clue that the patient has suffered a stroke is a bucket or ice pack next to or near the patient. This could be considered evidence that the patient has experienced nausea, vomiting, or headache, common complaints of many patients with stroke.

**Primary Assessment**

Immediately inspect the patient’s airway and suction any vomitus and secretions. If spinal injury is not suspected, place the patient in a lateral recumbent (recovery or coma) position. If spinal injury is suspected, perform a jaw-thrust maneuver to open the airway and provide manual in-line stabilization with the patient in a supine position. A patient with an altered neurological status may not be able to control his own airway. If the muscles supporting the tongue relax or become paralyzed, the support to both the tongue and epiglottis is lost. The tongue will fall back and occlude the pharynx. The epiglottis will flap forward and partially or completely block the airway at the level of the larynx. The gag reflex may be lost. In the instance...
of an acute stroke, the muscles of the throat may also be paralyzed. This would prevent the patient from swallowing adequately and could lead to aspiration of secretions.

Insert an oropharyngeal or nasopharyngeal airway if needed. Because the brain controls breathing rate and depth, it is possible to find inadequate breathing or unusual breathing patterns in the stroke patient. If the patient requires ventilation, place the patient in a supine position and begin positive pressure ventilation with supplemental oxygen connected to the device. If the patient is breathing adequately and the \( \text{SpO}_2 \) is \( \geq 94\% \) and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. Oxygen therapy should be guided by the level of oxygen saturation in the blood (\( \text{SpO}_2 \) reading) and presenting signs and symptoms and not by a predetermined oxygen concentration, liter flow, or device. If the \( \text{SpO}_2 \) is \( \leq 94\% \) or signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, administer oxygen via a nasal cannula at 2 to 4 lpm to maintain an \( \text{SpO}_2 \) reading of \( \geq 94\% \).

In the patient with a neurological deficit, you should not jump to conclusions when assessing the patient’s responsiveness. For instance, if you pinch the patient’s right hand and he does not respond, you can’t assume that he is unable to feel pain or sensation. He may be paralyzed on the right side; that is, he may be able to feel pain but be unable to move in response to the pain. Confirm the finding in another extremity.

**Secondary Assessment**

Any patient presenting with a sudden weakness of the face, hand, arm, or leg; trouble speaking or stuttering; difficulty seeing in one or both eyes; problem walking or a loss of balance or coordination; confusion; dizziness; or a sudden onset of a severe headache should be suspected of having suffered a stroke. Some information specific to stroke that can be collected in the physical exam is important to note and report to the emergency department. If the patient is unresponsive, you will perform a physical exam and obtain baseline vital signs before obtaining the history. If the patient is responsive, you will take the history before performing the physical exam and obtaining vitals. Regardless of whether you start with the history or with the physical exam, keep in mind that paralysis or a loss of speech is very frightening to the patient. You must remain calm and confident and continuously reassure the patient.

**Physical Exam.** The physical exam will be a rapid head-to-toe assessment. Any patient with loss of motor or sensory function, speech difficulties, or an altered mental status may be suffering from a head injury. Carefully inspect and palpate the head to determine if there is any evidence of trauma. If evidence of trauma exists, a head injury may be the reason for the neurological deficits being experienced by the patient. However, the patient may have experienced the neurological deficit first, causing him to fall, resulting in an injury to the head. Always have a high index of suspicion and report all your findings, including the scene characteristics.

Inspect the face for a drooped appearance on one side by instructing the patient to look up and smile or show his teeth (see information on the Cincinnati and Los Angeles stroke screens, later). An abnormal finding would be a drooped appearance in which one side does not move symmetrically or as well as the other (Figures 18-3a and 18-3b ■).

**FIGURE 18-3** (a) The face of a nonstroke patient has normal symmetry. (b) The face of a stroke patient often has an abnormal, drooped appearance on one side. (© Michal Heron)
Listen for garbled sounds or slurring when the patient speaks. Have the patient say the following phrase to assess his speech capability: “You can’t teach an old dog new tricks.” An abnormal finding would be if the patient said the wrong words, slurred words, was not able to say the phrase at all, uttered a completely unrelated phrase, or didn’t understand your directions.

Note the patient’s ability to obey your commands such as to repeat a phrase or to “Squeeze my fingers” or to “Wiggle your toes.” If the patient does not obey all of the commands, it is likely the stroke has affected his thought process and he does not understand what you are asking him to do. If he obeys only certain commands, he may be unable to obey the others because of a neurological deficit such as paralysis to one side of the body.

If you find the patient walking, note his movement and the manner in which he is walking. An abnormality such as unsteadiness can indicate a neurological deficit.

When assessing the extremities, you may find a reduction in the sensory and motor function on one side of the body. The patient may lack the ability to feel your touch or to feel pain and may display weakness or paralysis. Check the grip strength in the upper extremities by having the patient grasp and squeeze your fingers. Have the patient push and pull up against your hands with his feet to assess for equality of strength in the lower extremities. Note any differences in strength between the right and left sides and the upper and lower extremities. Assess for arm drift (Figures 18-4a and 18-4b) by instructing the patient to extend his arms, palms up, with eyes closed for 10 seconds. Note a downward drift or drop of one extremity. It is important to perform the assessment as quickly as possible and not delay transport in order to do a detailed neurological examination. Time is brain! That is, a delay in getting the patient to an appropriate stroke care facility could lead to greater brain ischemia and more extensive permanent damage.

When performing a neurological examination on a responsive patient who presents with any suspected signs or symptoms of stroke, you should use one of the validated stroke screening evaluation tools, either the Cincinnati Prehospital Stroke Scale or the Los Angeles Prehospital Stroke Screen (LAPSS).

The Cincinnati Prehospital Stroke Scale (Figure 18-5) tests for (1) facial droop by having the patient show his teeth or make a smile; (2) arm drift by having the patient close his eyes and hold both arms straight out in front of him for 10 seconds; and (3) abnormal speech pattern and muscle paralysis by having the patient say, “You can’t teach an old dog new tricks.”

The LAPSS takes into consideration other possible causes of altered mental status, such as hypoglycemia, hyperglycemia, or seizures, and also requires a physical test of asymmetry (unequal amount) of strength. The information gathered in the LAPSS (Figure 18-6) is (1) age greater than 45 years, (2) history of seizures or epilepsy, (3) duration of symptoms, (4) wheelchair or bedridden status of patient, and (5) blood glucose level. Asymmetry of strength is assessed by testing facial smile or grimace, grip, and arm strength.

Both screening tools are highly sensitive and specific. Any one abnormality in the physical tests of either CPSS or LAPSS is highly suggestive of stroke. According to the 2010 American Heart Association guidelines, the presence of a single abnormal finding on the CPSS has a sensitivity of 59 percent and a specificity of 89 percent when scored by prehospital care providers. Similarly, 93 percent of the patients who have suffered an acute stroke will respond yes or unknown with findings on the LAPSS, and 97 percent of the patients who present with positive findings on the LAPSS will have
suffered an acute stroke. It is important to perform one of these evaluations on any patient suspected of having a stroke.

Any one of the following physical exam findings is strongly suggestive of a stroke:

- There is facial droop of one side of the face when the patient is asked to smile or show his teeth.
- One arm does not move or one arm drifts downward when the patient’s arms are extended outward for 10 seconds with his eyes closed.

### Cincinnati Prehospital Stroke Scale

<table>
<thead>
<tr>
<th>Sign of Stroke</th>
<th>Patient Activity</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Facial droop</td>
<td>Have patient look up at you, smile, and show his teeth.</td>
<td>Normal: Symmetry to both sides. Abnormal: One side of the face droops or does not move symmetrically.</td>
</tr>
<tr>
<td>Arm drift</td>
<td>Have patient lift arms up and hold them out with eyes closed for 10 seconds.</td>
<td>Normal: Symmetrical movement in both arms. Abnormal: One arm drifts down or asymmetrical movement of the arms.</td>
</tr>
<tr>
<td>Abnormal speech</td>
<td>Have the patient say, “You can’t teach an old dog new tricks.”</td>
<td>Normal: The correct words are used and no slurring of words is noted. Abnormal: The words are slurred, the wrong words are used, or the patient is aphasic.</td>
</tr>
</tbody>
</table>

### Los Angeles Prehospital Stroke Screen (LAPSS)

**Considerations**

- Age greater than 45 years
- No history of seizures or epilepsy
- Duration of symptoms is less than 24 hours
- Patient is not wheelchair bound or bedridden
- Blood glucose level between 60 and 400 mg/dL

**Physical exam to determine unilateral asymmetry**

- A. Have patient look up, smile, and show teeth
- B. Compare grip strength of upper extremities
- C. Assess arm strength for drift weakness

**Equal**

**FIGURE 18-5** The Cincinnati Prehospital Stroke Scale.

**FIGURE 18-6** The Los Angeles Prehospital Stroke Screen (LAPSS).
The patient slurs his words, uses wrong words, or is unable to speak when asked to repeat the phrase “You can't teach an old dog new tricks.”

There is weak or no grip on one side of the body when asked to squeeze your fingers.

When assessing the baseline vital signs, pay attention to the systolic and diastolic blood pressure. Carefully document both readings and repeat every 5 minutes. Hypertension (high blood pressure) may have actually caused the nontraumatic brain injury or may be a sign of increased pressure within the skull. Unequal pupils or abnormal eye movements or gaze are also significant signs of a possible brain injury (either traumatic or nontraumatic).

Hypoglycemia can sometimes produce signs and symptoms very similar to those of stroke, especially in the elderly. Some hypoglycemic patients may present with confusion and neurological deficits that appear to be due to a stroke. The patient may not have a major alteration in his mental status. If your protocol permits, check the blood glucose level of any patient who presents with an altered mental status or neurological deficits. A patient who has just suffered a seizure may also present with neurological deficits. These deficits, including paralysis, may last up to several hours after the seizure. A good history may provide key information indicating that the paralysis is due to a seizure and not a stroke. However, also keep in mind that strokes may cause seizures.

**ASSESSMENT TIPS**

Some signs and symptoms of stroke are also common to other conditions. The condition that is most commonly misdiagnosed as stroke is hypoglycemia. If possible, assess the blood glucose level in the patient exhibiting signs and symptoms of stroke.

**History.** During your history, look for medical alert tags, collect the patient's prescription and nonprescription medications, and don't forget to look in the refrigerator for a vial of insulin, used to treat diabetes. Remember that diabetics may be hypoglycemic, and patients who are hypoglycemic may show signs and symptoms similar to those of a stroke patient, especially if the patient is elderly.

Try to gain as much information from the patient as possible. If the speech center of the brain has been affected, the patient may be unable to talk. Yet, don't assume that the patient cannot understand. Determine if the patient can respond to your commands by asking him to blink his eyes or squeeze your finger if he understands. If he is able to understand and make some type of gesture or motion, you can still obtain a history from the patient with the use of questions that can be answered “yes” and “no.” For example, you may instruct the patient to blink his eyes twice for yes and once for no. Answers to the following questions will guide you in your emergency care of the patient:

- **When did the symptoms begin?** This is crucial in establishing the time of onset of the stroke. Try to gather from relatives or bystanders when the first sign or symptom appeared. Since the drugs used to dissolve the clot are typically administered within 3 to 4.5 hours of the onset of the stroke, passing this information on to the hospital is critical. The hospital staff can then gauge how much time has expired and the course of treatment. Time is very precious and the transport must occur rapidly to a medical facility that can manage a stroke patient.
- **Is there any recent history of trauma to the head?** Although you may have ruled out trauma while sizing up the scene, it is important to note if the patient has suffered a head injury within the last few weeks.
- **Does the patient have a history of previous stroke?** For instance, the patient may have already lost speech, sensory, or motor function from a previous stroke. In this case the present neurological deficit may be either the result of another stroke or related to some cause other than a stroke or nontraumatic brain injury.
- **Was there any seizure activity noted prior to your arrival?** If so, you should be prepared for the patient to experience a seizure again. (Seizures will be covered in Chapter 19, “Seizures and Syncope.”)
- **What was the patient doing at the time of onset of the signs and symptoms?** The activity or lack of activity may point to a traumatic or nontraumatic cause.
- **Does the patient have a history of diabetes?** (Diabetes will be covered in Chapter 20, “Acute Diabetic Emergencies.”)
- **Has the patient complained of a headache? A stiff neck?** When collecting the history, it is especially important to note if the patient complained of a headache prior to becoming unresponsive or if the patient is currently complaining of a headache. Ask and document if the patient at any time states, “This is the worst headache I’ve ever had in my life,” or something similar. This is consistent with strokes caused by bleeding in or around the brain.
- **Has the patient complained of dizziness, nausea, vomiting, or weakness?**
- **Has the patient experienced any slurred speech?**

The following questions will provide useful information to the hospital personnel who will be receiving the patient. If the patient’s mental status is deteriorating, the hospital staff may be unable to get this information later and will need to rely on the information you are able to obtain.
• Does the patient take any oral anticoagulant drugs?
• Does the patient have a history of hypertension (high blood pressure)?
• Has the patient taken amphetamines, cocaine, or some other stimulant drug?
• Was the onset of signs and symptoms gradual or sudden?
• Did the signs and symptoms get progressively worse or better?
• Did the paralysis or weakness affect one part of the body first and then progress to other areas?
• Does the patient have a history of atrial fibrillation or irregular heartbeat?

**Signs and Symptoms.** The patient can have a wide range of signs and symptoms depending on the extent and location of the stroke. As noted earlier, the three most common findings are facial droop, arm drift, and speech disturbances. Others include (Figure 18-7 ■):

- Altered mental status ranging from dizziness or sudden confusion to complete unresponsiveness
- Sudden onset of paralysis (hemiplegia) or weakness (hemiparesis) to the face, arm, hand, or leg, especially to one side of the body
- Numbness or loss of sensation on one side of the body
- Speech disturbances—slurred, garbled, or incomprehensible speech (dysarthria) to complete loss of speech
- Loss of control of the bladder or bowel
- Unequal pupils
- Deterioration or loss of vision in one or both eyes, double vision
- Eyes turned away from the side of the body that is paralyzed
- Nausea and vomiting
- Sudden onset of severe headache
- Seizure activity
- Stiff neck (late symptom)
- Inability to understand what you are saying (sensory or receptive aphasia)
- Inability to form words to talk (expressive or motor aphasia)
- Incooordination of the extremities, usually on one side
- Poor balance, clumsiness, or difficulty in walking (ataxia)
- Hearing loss to one side
- Light or sound sensitivity
- Vertigo
- Dizziness
- Vomiting
- Ignoring one side of the body

![Figure 18-7](image)

Stroke and transient ischemic attack (TIA) are conditions that may result from nontraumatic brain injury. Loss of speech, sensory, or motor function and altered mental status are among the possible signs and symptoms. Facial asymmetry is a common sign.
In some types of stroke, the signs and symptoms may progress and the patient’s condition may continue to deteriorate. This is particularly true of the mental status, speech disturbance, numbness, weakness, and paralysis. For example, you may find a patient who has weakness to the right arm and leg, has slightly slurred speech, and obeys your commands. By the time you arrive at the hospital, the patient is completely paralyzed on the right, is unable to speak, and responds to only painful stimuli.

**Assessment Tips**

Hypotension is a rare finding in the stroke patient.

### The Dangers of Administering Too Much Oxygen in Stroke

Like the acute coronary syndrome, as described in Chapter 17, stroke is a reperfusion condition. In stroke, a cerebral artery is occluded or ruptured, which cuts off blood supply to a distal area of brain tissue. During this period of interrupted perfusion, there is an inflammatory response and the release into the ischemic brain tissue of damaging molecules made from oxygen, which are referred to as free radicals.

Blood restored to an area of brain tissue that was once ischemic from low blood flow or occlusion of a vessel is called reperfusion. The oxygen in the blood flowing to the reperfused brain tissue increases the production of free radicals, which directly damage brain cell membranes and other cellular components and result in brain cell death. A higher oxygen level in the blood results in a greater production of damaging free radicals and greater brain cell and tissue death. This does not occur during the hypoxic state but rather occurs when blood flow has been restored and the brain cells are receiving oxygen again.

Considering the response of the tissue undergoing reperfusion (increase in production of free radicals), it makes sense that the more oxygen supplied to the brain tissue the greater the tissue damage. Thus, while it is necessary to reverse any hypoxia as you manage the stroke patient, it is also extremely important not to deliver more oxygen than needed. The more oxygen you administer to the patient with normal blood oxygen saturation, the greater the cell damage you can cause when the brain cells are reperfused with blood containing high levels of oxygen.

This explains why it is extremely important to limit oxygen therapy in the stroke patient. It is recommended that oxygen be provided only to stroke patients with an SpO2 < 94% or if an SpO2 is unknown. In order to limit its concentration in the blood, oxygen should be administered via a nasal cannula starting at 2 lpm and only enough should be administered to reverse the hypoxia. It may be necessary to increase the liter flow to reach an SpO2 of 94%. Once the SpO2 reaches 94%, the liter flow should be maintained or adjusted to keep the SpO2 at 94%.

In summary: hyperoxegenating the stroke patient will likely lead to greater brain cell death.

### Emergency Medical Care

If your assessment reveals an injury, provide care for that injury, including spinal stabilization. In addition, if the patient displays an altered mental status or a loss of speech, sensory, or motor function, or if stroke is suspected, provide the following care:

1. **Maintain a patent airway.** Airway compromise in the stroke patient is common. It may be necessary to insert an oropharyngeal or nasopharyngeal airway. Typically, the nasopharyngeal airway is preferred because it is better tolerated by the patient.

2. **Suction secretions and vomitus.** Since vomiting is associated with a brain injury or stroke, be prepared to remove vomitus by suctioning.

3. **Be prepared to assist ventilation.** As the patient deteriorates, breathing may become inadequate. If the rate or quality of breathing is inadequate, begin positive pressure ventilation with supplemental oxygen. It is important to recognize early signs of respiratory failure. Inadequate breathing could drastically increase injury to the brain because of decreased oxygen flow to the brain and a buildup of carbon dioxide.

   If the patient is unresponsive and has unequal pupils or posturing and is breathing inadequately, hyperventilation at a rate of 20 ventilations per minute with supplemental oxygen might be considered. Follow your local protocol or contact medical direction, since hyperventilation of patients with increased pressure inside the skull is considered controversial and may actually worsen the blood flow to the brain.

4. **Maintain adequate oxygenation.** According to the AHA 2010 guidelines, if the SpO2 reading is less than 94%, the patient complains of dyspnea, or signs and symptoms of hypoxia, heart failure, or shock are present, administer oxygen by nasal cannula at 2 to 4 lpm. High-concentration oxygen is no longer considered routine for the stroke patient unless severe signs of hypoxia are present. Always follow your local protocol.

5. **Position the patient.** If the patient is unable to protect his own airway because of a reduction in his mental status, place him in a left lateral recumbent position (Figure 18-8). Place the responsive patient in-line stabilization with the patient supine. If the responsive patient in a supine position. If the patient wants to be placed in a semi-Fowler’s position, do not elevate the head and chest more than 30 degrees (Figure 18-9). If spinal injury is suspected, perform a jaw-thrust maneuver to open the airway and provide manual in-line stabilization with the patient supine. If the
Reassessment

Perform a reassessment every 5 minutes. Pay special attention to the status of the airway, breathing, circulation, and mental status. This is extremely important since many stroke patients deteriorate rapidly and significantly. Pay particular attention to the patient’s airway as the mental status changes. Repeat and record vital signs. Communicate any changes in the patient’s condition to the receiving facility.

Summary: Assessment and Care

To review assessment findings that may be associated with stroke and emergency care for a patient suspected of having suffered a stroke, see Figures 18-10a, 18-10b, and 18-11.

HEADACHE

A headache may be a condition in itself or a symptom of another condition such as stroke, a brain tumor, or a brain infection. Pain associated with a headache can have a sudden onset, be constant, or continuously recur. The headache may be isolated to one area of the head or may be generalized and felt throughout the head. The pain could be described as mild, moderate, or severe.

Types of Headache

Headaches can be categorized as the following:

- **Vascular headaches** occur as a result of dilation or distention of vessels or inflammation within the cranium. Migraine headaches are thought to be caused by spasm of vessels followed by vasodilation and a change in the chemicals that transmit nervous impulses in the brain. Migraines are often described as throbbing and may be generalized or localized to one side of the head. The patient also commonly experiences sensitivity to light (photosensitivity), nausea, vomiting, and sweating. Migraines may be preceded by an aura, such as blind spots, bright shimmering lights, weakness to one side of the body, numbness or tingling to one side of the body, visual or hearing hallucinations, double vision, uncoordination, or syncope. A vascular headache may also be caused by hypertension (high blood pressure) typically reaching a diastolic pressure of 120 mmHg for a headache to occur.

- **Cluster headaches** are similar to migraines because they are believed to have a vascular origin. The pain is usually found on only one side of the head or face in the temporal region or around the eye and is excruciating. The patient may also complain of excessive tear production on the side of the pain, nasal congestion or runny nose (rhinorrhea), and nausea. Upon assessment, you might find facial sweating,
Assessment Summary

STROKE
The following are findings that may be associated with a stroke emergency.

Scene Size-up
Is neurological deficit due to trauma or a medical problem?
Look for:
- Mechanism of injury
- Alcohol, drugs, or other substances that are commonly abused
- Position and location of patient
- Bucket or ice pack next to bed

Primary Assessment

General Impression
- Vomitus or secretions in mouth
- Slurred or incomprehensible speech
- Paralysis to one side of body

Mental Status
- Alert to unresponsive
- Able to understand but unable to speak
- Unable to understand or obey commands
- Disoriented

Airway
- Obstruction by tongue
- Obstruction by vomitus or secretions
  (Insert a nasopharyngeal or oropharyngeal airway in the unresponsive patient.)
- Drooling or inability to swallow

Breathing
- Shallow respirations
- Irregular respirations
- Absent respirations

Circulation
- Heart rate may be increased or decreased.

Status: Priority patient

Secondary Assessment

History
- Signs and symptoms:
  - Altered mental status

Numbness or loss of sensation to one side of the body
Weakness or paralysis to the hand, arm, leg, or face on one side of the body
Speech disturbances (slurred, incomprehensible)
Loss of bladder and bowel control
Unequal pupils
Visual disturbances (loss of vision in one eye, blurred vision, loss of visual field)
Nausea and vomiting
Headache (severe in stroke due to hemorrhage)
Seizure
Stiff neck
Facial droop

Ask questions regarding the following:
- Anticoagulant drugs?
- History of hypertension?
- Abuse of amphetamines, cocaine, or other stimulant drug?
- Onset gradual or sudden?
- Signs and symptoms progressively get worse?
- Paralysis affects one side of body first?

Physical Exam
- Head, neck, and face
- Eyelid droop
- Facial droop
- Abnormal eye movements or gaze
- Extremities
  - Weak or paralyzed on one side
  - Numbness
  - Unequal grip strength on one side of body
  - Loss of sensation to one side of body
- Arm drift

Baseline Vital Signs
- BP: elevated or normal
- HR: normal or decreased
- RR: normal, decreased, increased, or irregular
- Skin: normal
- Pupils: possibly unequal and dilated
- Blood glucose level: normal
- SpO2: 94%

restlessness or agitation, facial flushing or pallor, scalp or facial tenderness, and drooping eyelids.

- Tension headache is thought to be caused by contraction of the muscles of the neck and scalp. The pain is usually described as “tight” or “viselike.” This is the most common type of recurring headache found in children, adolescents, and adults. The patient may wake in the morning with a headache that worsens throughout the day. The pain occurs to both sides of the head and is described as throbbing, aching, squeezing, “bandlike,” or forceful pressure. The pain is usually felt in the frontal, temporal, and occipital
Emergency Care Protocol

STROKE

1. Establish and maintain an open airway. Insert a nasopharyngeal or oropharyngeal airway if the patient is unresponsive.
2. Suction secretions as necessary.
3. If breathing is inadequate, provide positive pressure ventilation with supplemental oxygen at a minimum rate of 10–12 ventilations/minute for an adult and 12–20 ventilations/minute for an infant or child.
4. According to the AHA 2010 guidelines, if the SpO₂ reading is less than 94% the patient complains of dyspnea, or signs and symptoms of hypoxia, heart failure, or shock are present, administer oxygen by nasal cannula at 2 to 4 lpm. High-concentration oxygen is no longer considered routine for the stroke patient unless severe signs of hypoxia are present. Always follow your local protocols.
5. Place the patient in a lateral recumbent position if unresponsive and if no spinal injury is suspected. If responsive and no spinal injury is suspected, elevate the head no greater than 30 degrees.
6. Obtain a blood glucose reading if your protocol permits.
7. Transport.
8. Perform a reassessment every 5 minutes.

Assessment

During scene size-up, look for clues that a headache may be associated with a toxic exposure. Assess the airway, ventilation, and oxygenation status. Apply oxygen based on the SpO₂ and patient presentation. Oxygen may relieve a cluster headache. Assess pulse and perfusion. Pain will often trigger the sympathetic nervous system and cause tachycardia and pale, cool, clammy skin. Perform a history and secondary assessment looking for any underlying cause of the headache. Assess the blood glucose level if permitted.

With any of the following signs or symptoms, suspect a serious underlying condition (Table 18-1).

- Altered mental status
- Motor or sensory deficit
- Behavior change
- Seizure
- First experience of this type of headache with an abrupt onset
- Worsening of pain with coughing, sneezing, or bending over
- Fever or stiff neck
- Change in the quality of a chronic headache

Emergency Medical Care

1. Establish and maintain an adequate airway. This may be necessary if the patient’s mental status is deteriorating.
2. Be prepared to suction. Vomiting may occur with the headache.
3. Assess and maintain adequate ventilation. If the tidal volume or respiratory rate is inadequate, begin positive pressure ventilation with oxygen connected to the ventilation device.
4. Maintain adequate oxygenation. If the patient is breathing adequately and the SpO₂ is ≥94% and no other signs of respiratory distress, hypoxia, hypoxemia, or poor perfusion are present, there may be no need to administer supplemental oxygen. Oxygen therapy should be guided by the level of oxygen regions of the head and often radiates to the neck and shoulders. There is no nausea or vomiting associated with a tension headache; however, the patient may complain that he has no appetite. The onset is usually more gradual than the onset of a migraine.

- Organic, traction, or inflammatory headaches are a result of tumors, infection, stroke, or inflammatory disorders within the cranium such as meningitis, hemorrhagic stroke, and tumor.

**FIGURE 18-10b** Emergency care protocol: stroke.
Emergency Care Algorithm: Stroke

Mechanism of injury present?

Yes

Consider manual in-line stabilization

Assess mental status

Alert with signs of stroke

Consider oxygen administration

Assess circulation

Secondary Assessment

Blood glucose <60 mg/dL

Yes

Consult medical direction and consider diabetic emergency protocol

No

No

Altered: unresponsive or unable to obey commands

Airway open?

Yes

Suction if necessary

Head-tilt, chin-lift or jaw-thrust maneuver

Oro- or nasopharyngeal airway

Assess breathing

Adequate

Inadequate

Administer oxygen

PPV with O₂

Assess circulation

Rapid secondary assessment

Transport

Reassessment

No

PPV = positive pressure ventilation
Cream = assessment
Green = key decision points
Blue = interventions

5. **Place the patient in a position of comfort.** The patient may be more comfortable lying flat, on his side, or in a seated position. It may be necessary to keep the lights dim in the back of the ambulance because of the light sensitivity experienced by some patients.

6. **Always be prepared to treat for seizures and transport to a medical facility.**

---

**Summary**

Altered mental status may occur as a result of a wide variety of conditions involving both traumatic and medical causes. The causes may be structural or metabolic-toxic. Your primary responsibility is to ensure that you have established and are maintaining an adequate airway, ventilation, oxygenation, and circulation.

Stroke is a common emergency that can lead to devastating and long-term disability for the patient. Some signs and symptoms of stroke are very subtle. Have a high index of suspicion and consider all signs and symptoms when dealing with the possible stroke patient. When providing emergency care, early recognition of the stroke, immediate transport, and notification prior to your arrival are crucial. The majority of your actual emergency care will be supportive.

There are two types of stroke: ischemic stroke and hemorrhagic stroke. Ischemic stroke is further categorized as thrombotic or embolic. The most common type of stroke is a thrombotic stroke.

The Cincinnati Prehospital Stroke Scale (CPSS) and the Los Angeles Prehospital Stroke Screen (LAPSS) are two evaluation tools used by EMS to identify possible stroke in a patient. These are both predictive screening tools for stroke. The most common signs and symptoms seen in stroke are sudden onset of weakness, paralysis, or numbness to the arm, hand, leg, or face on one side of the body; confusion or inability of the patient to respond to your questions or commands; trouble speaking; difficulty in vision in one or both eyes; difficulty walking or loss of coordination or balance; or a sudden onset of a severe headache.

Headache may be a condition itself or an indication of a serious underlying condition such as stroke, meningitis, hypertension, poisoning, toxic inhalation, or a number of other conditions. Carefully assess the patient and pay particular attention to any evidence of deterioration in the mental status or vital signs.

---

**Case Study Follow-up**

**Scene Size-up**

You have been dispatched to a 73-year-old female patient who was found by her husband lying in bed. As you arrive on the scene, the husband meets you at the front door, introduces himself as Mr. Stein, and leads you into the house and up to the second floor bedroom. According to her husband, the patient is unable to move the right side of her body. As you scan the scene, you notice nothing out of the ordinary. The house appears to be extremely well kept, yet the smell of urine and feces permeates the air upon entering the bedroom. You notice bottles of prescription medications on the nightstand next to the bed.

**Primary Assessment**

The patient is an elderly female who is still in her nightgown. As you approach the patient, you say, “Mrs. Stein?” Mrs. Stein opens her eyes and attempts to answer. Her speech is severely slurred and her face is pulled and drooping on the right side. Her breathing is adequate at a rate of approximately 20 per minute. Her radial pulse is strong and estimated at 70 beats per minute. Her skin is warm and dry.

**Secondary Assessment**

Mrs. Stein’s slurred and garbled speech makes it difficult to understand what she says. She is not alert...
enough to respond appropriately to your questions, so you decide to begin with the physical exam rather than the history, and you perform a rapid assessment. Her head shows no evidence of trauma. Her pupils are equal and reactive. She has an obvious facial droop to the right side when asked to smile and show her teeth. Her chest is rising and falling symmetrically and the breath sounds are equal bilaterally. Her abdomen is soft and no tenderness or rigidity is noted. Her pelvis is stable with no tenderness on palpation. Mrs. Stein is able to obey your commands, so you check and compare her strength in all four extremities. When asked to squeeze your fingers, she has good grip strength on the left, but grip strength on the right is absent. She cannot lift her right arm when asked to put her arms out in front of her to check for arm drift. When asked to push up against your hands with her feet, the strength is good on the left, but again absent on the right. The posterior of her body shows no abnormalities. You find no medical alert tags.

While you are performing the rapid assessment, your partner is taking baseline vital signs. The blood pressure is 198/110 mmHg. The heart rate is 74 per minute and irregular. The respirations are 22 per minute and of normal depth. The skin is normal in color, warm, and dry. Her SpO2 is 97%; therefore you elect not to administer oxygen. Her blood glucose level is 98 mg/dL.

Next, you obtain the history, primarily from Mr. Stein. He states that his wife’s speech was slurred when she woke up this morning. (Because of this, the time of onset cannot be definitively determined.) Unlike now, however, he was still able to understand her. She complained, “I can’t move my right arm or leg,” and was disturbed that she had soiled the bed. Mr. Stein immediately went downstairs and called 911. He states, “It seems that she has gotten worse since I found her this way.” He does not know of any known allergies his wife has. When asked if she takes any medications, he says, “She does take a water pill, a pill for her heart, and a pill for her blood pressure.”

Your partner places the medications from the nightstand into a paper bag to be transported with the patient. According to Mr. Stein, his wife had a heart attack 2 years ago, and she has high blood pressure. He claims that her last oral intake was a cup of coffee last night at about 10:30. He did not notice anything unusual and she did not complain of anything before going to bed or during the night.

You and your partner place Mrs. Stein on her left side on the stretcher. You secure Mrs. Stein to the stretcher, ensuring that the paralyzed extremities are well protected, and transfer her to the ambulance.

Reassessment
Mrs. Stein’s mental status does not change while en route to the hospital. Her airway remains open and clear. Her breathing is adequate at a rate of 22 per minute and the radial pulse is strong at a rate of 74 per minute. Her skin remains warm, dry, and a normal color. She continues to attempt to talk, but her speech remains slurred and garbled. The SpO2 continues to read 97%. You record the vital signs and report Mrs. Stein’s condition to the hospital.

Upon arrival at the emergency department, you provide an oral report of Mrs. Stein’s condition as you assist in transferring her to the hospital bed. You complete your prehospital care report, restock the ambulance, notify dispatch you are in service, and prepare for another call.

Later that morning, you return to the emergency department to pick up some equipment. While there, you check on Mrs. Stein’s status and learn that she has suffered a stroke and is likely to have permanent paralysis to the right side of her body.

Case Study Follow-up continued

IN REVIEW
1. List possible causes of an altered mental status.
2. Explain why the airway and breathing must be closely monitored in a patient with an altered mental status or stroke.
3. List several signs and symptoms of stroke.
4. List the steps in the emergency care of the patient suffering from an altered mental status or stroke.
5. Compare and contrast stroke and TIA with regard to signs and symptoms, how they progress, and emergency medical care.
6. Describe the various types of headache.
7. List signs or symptoms associated with a headache that would indicate a serious underlying cause.
CRITICAL THINKING

You arrive on the scene and find a 68-year-old male patient whose wife states he suddenly began to slur his words. The patient is alert and responding to your questions. You note an obvious slur to his words in addition to a left facial droop. His respirations are 14 per minute with good chest rise. His radial pulse is irregularly irregular at a rate of 108 bpm. His skin is warm and dry. His SpO₂ is 92% on room air. His blood pressure is 242/128 mmHg. His blood glucose reading is 89 mg/dL. He has no known allergies and takes Lipitor. He has no significant medical history and last ate when he had lunch about 2 hours prior to your arrival. The patient was on the phone when the slurring suddenly began. He has obvious facial droop when you ask him to make a smile. His left arm drifts when he attempts to hold both arms out in front of his body. His pupils are equal and reactive. Breath sounds are equal and clear bilaterally. Good pulses are found in all the extremities; however, the left arm and leg exhibit weakness and loss of sensation.

1. What is the oxygenation status of the patient?
2. How would you manage the oxygenation status of the patient?
3. What type of stroke do you suspect the patient suffered?
4. What signs and symptoms would cause you to believe the patient suffered a stroke?
5. How would you manage the patient?
6. What is the significance of the pulse rhythm?
The following items provide an overview to the purpose and content of this chapter. The Standard and Competency are from the National EMS Education Standards.

**STANDARD** • Medicine (Content Area: Neurology)

**COMPETENCY** • Applies fundamental knowledge to provide basic emergency care and transportation based on assessment findings for an acutely ill patient.

**OBJECTIVES** • After reading this chapter, you should be able to:

19-1. Define key terms introduced in this chapter.
19-2. Describe the various ways that seizures can present.
19-3. Discuss the pathophysiology of seizures.
19-4. Explain the concerns associated with prolonged or successive seizures.
19-5. Describe the assessment and emergency medical care of patients with tonic-clonic, simple partial, complex partial, absence, and febrile seizures.
19-6. Anticipate bystander reactions to patients having seizures and take measures to stop unnecessary or inappropriate interventions.
19-7. Describe the assessment and emergency medical care of patients in a postictal state.
19-8. Describe the assessment and emergency medical care of patients who are unresponsive, actively seizing, or in status epilepticus.
19-9. Recognize situations in which the patient who is having or has had a seizure must be a higher priority for transport.
19-10. Discuss the role of blood glucose determination in patients who have had a seizure.
19-11. Discuss relevant questions to ask while gathering a history of the seizure activity.
19-12. Describe common causes of syncope.
19-13. Describe the scene size-up, assessment, and emergency medical care of patients with syncope, including differentiating syncope from seizure.

**KEY TERMS** • Page references indicate first major use in this chapter. For complete definitions, see the Glossary at the back of this book.

- status epilepticus p. 548
- syncope p. 556
INTRODUCTION

A seizure is a sudden onset of random, continuing discharges of electrical activity in the brain, which can lead to unusual manifestations, from staring spells to gross muscle contraction. Most (but not all) seizure activity is accompanied by an altered mental status. Many seizures are self-limiting and last only 2–3 minutes. Most often, the seizure will have stopped by the time EMS arrives on the scene. Frequently, emergency care will consist of assisting the patient during recovery and transporting him to the hospital.

Although seizures occurring in patients who have a history of a seizure disorder can be quite dramatic and frightening to observe, they are often not dangerous in themselves. However, the seizing patient can injure himself by falling or thrashing around. It is important for the EMT to recognize that seizures that are prolonged or are associated with life-threatening conditions or injuries such as head injury or stroke are abnormal and dangerous. Your prompt intervention in the prolonged or abnormal seizure may be life saving.

SEIZURE

A seizure is a sudden and temporary alteration in brain function caused by massive, continuing electrical discharges in a group of nerve cells in the brain. The abnormal electrical discharge typically produces changes in mental activity and behavior ranging from brief trance-like periods of inattention to unresponsiveness and the jerky muscle contractions known as a convulsion. A seizure is not a disease in itself but rather a sign of an underlying defect, injury, or disease.

A common cause of seizures is epilepsy, a chronic brain disorder characterized by recurrent seizures. There are approximately 125,000 newly reported cases of epilepsy each year. Although epilepsy is often thought of as a childhood disorder, only 30 percent of the new cases occur in children, and these occur most often in early childhood or at the onset of adolescence. Those over the age of 65 are another group with a high new-onset incidence of epilepsy.

If you have never seen a seizing person, you might easily mistake a seizure—or seizure phase—for a stroke, a behavioral disturbance, fainting, or simply daydreaming or lack of attention. What does a seizure “look” like?

The most common type of epileptic seizure, the generalized tonic-clonic seizure, is often called a grand mal seizure. Because these seizures rarely last more than a few minutes, the patient may be in a postictal state by the time you arrive on the scene. The postictal state follows the seizure and is the recovery period for the patient. During this period, the patient may be unresponsive, extremely sleepy, weak, and disoriented or may have strockelike symptoms such as paralysis. Because such a large number of muscles were contracting during the seizure, he will feel extremely tired. He will slowly but progressively regain complete responsiveness and orientation. This phase may last up to 30 minutes.

Epilepsy is only one cause of seizures. Seizures may also result from injuries or medical conditions other than epilepsy and may last much longer than the typical epileptic seizure. Seizure activity that is related to an injury or a medical condition may be an ominous sign of brain injury, even permanent brain damage. It is imperative that you not develop “tunnel vision” and assume that any seizure is caused by epilepsy. Also, patients with epilepsy may develop seizures from other causes, such as head injury. If the patient who suffers a seizure has no known history of a seizure disorder, you should suspect some medical or traumatic cause of the seizure other than epilepsy. During the scene size-up and the remainder of assessment, be alert for any clues to a cause other than epilepsy—for example, an
injury that must be managed. Also be aware that a heart attack, stroke, or other medical condition may be confused with a seizure or may produce a seizure.

It is imperative for you to assess and manage the altered mental status associated with the seizure and the postictal state. Prolonged seizures could result in significant airway and breathing compromise. Your task, as an EMT, is not to diagnose the type of seizure, but to assess for and manage any life-threatening conditions and provide reassurance to the patient.

Pathophysiology of Seizures

There are several types of seizures, and each has a variety of signs and symptoms. Some seizures might, at first glance, be mistaken for other conditions. For instance, the patient experiencing an absence seizure can be thought to be simply daydreaming, and the patient who is having a complex partial seizure could be mistaken for someone with a behavioral or psychological disturbance. So, while your treatment efforts will be focused on generalized seizure activity and managing any life threats, it is still important for you to recognize the types of seizures.

Seizures are categorized as either primary seizures or secondary seizures. Secondary seizures are also referred to as reactive seizures. Primary seizures in adults are usually due to a genetic or unknown cause. Primary seizures are categorized as generalized or partial seizures. Generalized seizures involve both hemispheres of the brain and the reticular activating system, which typically results in a loss of consciousness. Generalized seizure activity is usually characterized by rhythmic, tonic-clonic muscle contractions (convulsions). Partial seizures are typically related to abnormal activity in just one cerebral hemisphere. Partial seizures are either simple or complex. A patient who is suffering a simple partial seizure will remain conscious, whereas a complex partial seizure will normally produce an altered mental status or unresponsiveness.

Secondary or reactive seizures do not result from a genetic cause but occur as the result of an insult to the body, such as fever, infection, hypoxia, hypoglycemia, hyperglycemia, drug intoxication, drug withdrawal, eclampsia in pregnancy, degenerative brain diseases, or imbalances in the electrolytes in the body (Table 19-1). As a rule of thumb, secondary or reactive seizures are generalized in nature and do not produce partial-type seizures. Thus, the patient suffering a seizure from some type of insult to the body will suffer a full convulsive-type seizure. The key with this type of seizure is to identify and treat the underlying cause of the seizure activity. For example, if the seizure activity is due to hypoxia resulting from inadequate breathing, the most important emergency care you can provide that will stop the seizure and prevent it from recurring is to establish an airway and provide effective positive pressure ventilation with supplemental oxygen.

Reactive or secondary generalized seizures that are due to an insult to the body are extremely dangerous and can result in death if not treated promptly. These are totally different from seizures that are primary, in which the patient usually has a diagnosed history of a seizure disorder.

Status Epilepticus

A patient who suffers generalized motor seizures that last more than 5 minutes or seizures that occur consecutively without a period of responsiveness between them is considered to be in status epilepticus. This is a dire medical emergency that requires aggressive airway management, positive pressure ventilation with supplemental oxygen, and immediate transport to a medical facility. The longer the delay in treatment the greater the chance of the patient suffering permanent brain damage.

Types of Seizures

The type of seizure the patient experiences depends on whether it is primary or reactive and where in the brain the abnormal electrical activity is occurring. The following are the more common types of seizures.

Generalized Tonic-Clonic (Grand Mal) Seizure

A generalized tonic-clonic seizure was once referred to as a grand mal seizure. This type of seizure usually begins with abnormal electrical activity low in the cerebral cortex that spreads upward, affecting both cerebral hemispheres, and downward, affecting the reticular activating system (RAS). The RAS is responsible for wake/sleep activity. If the RAS is disturbed, the patient will lose consciousness. The involvement of both cerebral hemispheres contributes to the loss of consciousness and produces the characteristic jerky, convulsive motor activity.

### Table 19-1 Common Causes of Secondary Seizures

- High fever
- Infection
- Poisoning
- Hypoglycemia (low blood sugar)
- Hyperglycemia (high blood sugar)
- Head injury
- Shock
- Hypoxia
- Stroke
- Drug or alcohol withdrawal
- Dysrhythmias
- Hypertension (high blood pressure)
- Pregnancy complications (eclampsia)
- Blood electrolyte imbalance (sodium, calcium)
- Hyperthermia
- Idiopathic (unknown cause)
PATHOPHYSIOLOGY PEARLS

A generalized seizure typically involves both cerebral hemispheres (large lobes) of the brain and the reticular activating system (the wake/sleep system). This is what produces the unresponsiveness during the seizure.

The signs and symptoms of a generalized tonic-clonic seizure usually occur in the following six stages (Figure 19-1):

- **Aura.** The **aura** serves as a warning that a seizure is going to begin and involves some type of sensory perception by the patient. The aura may be a sound, an abnormal twitch, anxiety, dizziness, a smell or odor, an unpleasant feeling in the stomach, visual disturbance, or odd taste. Many patients will tell you that they knew they were going to seize because of the aura. However, generalized seizures do commonly occur without the preceding aura.

- **Loss of consciousness.** The patient loses consciousness sometime after the aura.

- **Tonic phase (muscle rigidity).** The patient’s muscles become contracted and tense, and the patient exhibits extreme muscular rigidity with arching of the back.

- **Hypertonic phase.** The patient has extreme muscular rigidity with hyperextension of the back.

- **Clonic phase (convulsion).** Muscle spasms then alternate with relaxation, producing the typical violent and jerky seizure activity of the clonic phase. During the convulsion, a loss of bowel and bladder control may result in involuntary urination and defecation. Also, the tongue, lips, or mouth may be bitten. The breathing may be shallow or absent. This phase usually lasts only 1–3 minutes.

- **Postictal state.** The **postictal state** is the recovery phase. The patient’s mental status is altered and may range from complete unresponsiveness to confusion and disorientation. The mental status progressively improves over time. The patient is exhausted and weak. A headache and temporary weakness to one side of the body (hemiparesis) may be present. The postictal phase generally lasts from 10–30 minutes. It could last much longer.

**Emergency Medical Care.** If the patient has a history of epilepsy with recurrent seizures, it is likely that the seizure activity has already stopped and the patient is in a postictal state by the time you arrive on scene. In this case, provide reassurance and conduct a thorough

![Figure 19-1](image)
assessment to ensure that the patient did not injure himself and that no abnormal signs or symptoms are present. If this is a typical seizure for the patient, and he refuses transport, follow local protocol and contact medical direction if necessary.

If the seizure presents as status epilepticus, provide the emergency medical care outlined in the “Assessment-Based Approach to Seizure Activity” section later in the chapter. Focus on establishing and maintaining an adequate airway, ventilation, oxygenation, and circulation. Remember that status epilepticus is a dire emergency that could result in damage to or death of brain cells, other tissue damage, and organ failure.

**Simple Partial Seizure**

A simple partial seizure is also known as a focal motor seizure or Jacksonian motor seizure. This type of seizure involves only one cerebral hemisphere. For this reason, it generally produces jerky muscle activity in one area of the body, arm, leg, or face. The patient cannot control the jerky movement. The patient remains awake and aware of the seizure activity because the reticular activating system and both cerebral hemispheres are not involved. The seizure activity may spread from one area of the body to another and sometimes progresses to a generalized tonic-clonic seizure. You should document where the seizure activity began and how it progressed. This information may be extremely helpful in identifying a cause and in the long-term treatment of the patient.

**Assessment Tips**

The term “complex” with regard to partial seizures typically refers to that which results in an alteration in mental status.

**Emergency Medical Care.** Speak calmly and reassuringly. Guide the person gently away from objects that may be hazardous to him or others. Stay with the person until he is completely aware of his surroundings. Because these seizures are recurrent in nature, he will most likely refuse transport. Consult medical direction or follow local protocol in this instance.

**Absence (Petit Mal) Seizure**

Absence or petit mal seizures, which are most common in children, are characterized by a blank stare, beginning and ending abruptly, and lasting only a few seconds. There may be rapid blinking, chewing, and lack of attention. The child is unaware of what is occurring during the seizure but then quickly returns to full awareness. No emergency care is necessary for the absence seizure. If this is a first-time observation of the seizure, however, medical evaluation should be recommended.

**Febrile Seizure**

Febrile seizures, caused by high fever, are most common in children between 6 months and 6 years of age. About 5 percent of children who have a fever will develop febrile seizures. These secondary or reactive generalized seizures are often very short and may not require emergency care; however, always assume that the seizures are serious, because you won’t be able to make the diagnosis without a medical evaluation. These seizures will be covered in more detail in Chapter 38, “Pediatrics.”
Assessment-Based Approach to Seizure Activity

**Scene Size-up**

Because a seizure could be a sign of head injury, look for a mechanism of injury that may suggest blunt or penetrating injury to the head. Also, check the environment for any evidence of poisoning, such as pill bottles and syringes. Look for prescription medications that may indicate a history of epilepsy, diabetes, or heart disease.

**ASSESSMENT TIPS**

Drug or alcohol withdrawal is a common cause of seizures. These are not epileptic seizures and need to be managed immediately.

**PATHOPHYSIOLOGY PEARLS**

A patient with a head injury may not present with seizures until months after the injury. The delayed seizure may be caused by the formation of scar tissue and abnormal electrical connections during the body's attempt to repair brain tissue.

The patient may no longer be seizing when you arrive on the scene but may be in a postictal state. Once responsive, the patient may refuse emergency care and transportation. This frequently occurs in public places where the bystanders call EMS. The epileptic patient, however, may be accustomed to the seizure activity and does not necessarily want or need emergency care. If this is the case, you might encourage him to go to the hospital for a checkup if the seizure was abnormal in any way. Always begin with the assumption that the seizure patient needs emergency care. Otherwise, follow local protocols.

You can’t force a patient to accept transport or treatment, but you do need to document the call and follow the proper patient refusal procedure. A postictal patient (one in the period of recovery from a seizure) may be confused and not in the best state of mind to refuse transport. If this is the situation, contact medical direction for further orders.

**ASSESSMENT TIPS**

The duration of the postictal state will vary from patient to patient and from seizure to seizure in the same patient. The signs of recovery may also vary.

If the patient is still seizing when you arrive, you will frequently find bystanders who are attempting to restrain the patient’s jerky body movements. The patient's movements should always be guided, rather than restrained, in order to prevent further injury. It may also be necessary to move objects away from the patient (Figure 19-2). Some people place spoons or other hard objects in the patient's mouth to prevent him from “swallowing his tongue,” which is anatomically impossible. Remove these objects immediately because they can easily cause injury to the mouth, tongue, teeth, and jaw or they can break and cause an airway obstruction. It is common for the patient to bite his tongue during the seizure; therefore, you may notice small amounts of blood around his mouth. The smell or sight of urine and feces may also be noted, as loss of bowel and bladder control is common during seizures.

Because seizure activity may mimic a heart attack and can result in short periods of apnea (absence of breathing), you may find a bystander performing CPR on the patient on your arrival. Quickly verify a pulse, and immediately stop any unnecessary care. Some cardiac arrests are preceded by seizure activity because of a lack of oxygen and blood to the brain. You should proceed with CPR, application of the automated external defibrillator (AED), and emergency care for cardiac arrest if no pulse is found.

**PATHOPHYSIOLOGY PEARLS**

The convulsive phase of a seizure causes the muscles in the body to contract and relax abnormally. Because the diaphragm is a large muscle, it also contracts and relaxes abnormally. This causes a temporary interruption in the patient’s normal ventilatory status. After a convulsive state ceases, the sympathetic nervous system will be activated and cause tachycardia, tachypnea, and possibly hypertension. The hyperventilation may help in restoring the oxygen depletion that occurred during the convulsive phase.

**Primary Assessment**

Form a general impression of the patient as you begin the primary assessment. Whether you find the patient actively seizing or in a postictal state, you should consider both of these an altered mental status that warrants close assessment of the airway, breathing, and circulation. The patient who is not responding to verbal stimuli following the seizure episode, the patient who is actively seizing, or the patient who has suffered more than one consecutive seizure without an intervening period of responsiveness is at the greatest risk for airway, breathing,
Assessing Patients in the Postictal State

- If the patient is talking without distress, it indicates an open airway and adequate breathing. The heart rate is commonly elevated and the skin warm and moist. Continue with the secondary assessment for the medical patient. If the seizure was self-limited and typical for that patient, emergency care may not be required.

Assessing Patients Who Are Unresponsive to Verbal or Painful Stimuli, Actively Seizing, or in Status Epilepticus

- Open the airway with a jaw-thrust or head-tilt, chin-lift maneuver. It may be necessary to insert a nasopharyngeal airway. Large amounts of saliva are produced during the seizure and the tongue is commonly bitten and bleeding. Suction any secretions, vomitus, or blood from the airway (Figure 19-3). Do not place your fingers in the mouth of the seizing patient or any unresponsive patient. He can easily bite down and cause you serious injury. Do not insert an oropharyngeal airway since the patient may regain his gag reflex and vomit.
- During a seizure, the chest wall muscles contract and restrict effective breathing. The patient may appear to have an airway obstruction and may be cyanotic. As long as the seizure does not last longer than 5 minutes or more than one seizure does not occur consecutively, this should not pose a major problem since respiration will quickly return to normal following the abnormal muscle activity. In the following circumstances, you should begin positive pressure ventilation with supplemental oxygen: the patient is severely cyanotic, the seizure has lasted for greater than 5 minutes from the time of onset (not from your arrival), or the breathing does not immediately become adequate following the episode.
- Note the skin temperature and color. High body temperatures are a common cause of seizures in infants and very young children. Hot skin may also indicate a high body temperature resulting from the excessive uncontrolled muscle movement in the adult. Cyanosis is a grave sign of inadequate oxygenation and requires a high concentration of oxygen. Administer supplemental oxygen to maintain an SpO2 of ≥94% if the breathing is adequate, or, as already noted, positive pressure ventilation with supplemental oxygen if breathing is inadequate.
- Ensure the presence of a pulse if the patient is unresponsive. Initiate CPR and apply the AED if the patient is pulseless. Check for and manage any serious bleeding that may have resulted from trauma.

The seizure patient should be categorized as a priority for transport if any of the following occurs:

Transport Priority Circumstances

- The patient remains unresponsive following the seizure.
- The airway, breathing, or circulation is inadequate following the seizure activity.
- A second generalized motor seizure occurs without a period of responsiveness between the seizure episodes (status epilepticus).
- A generalized motor seizure lasts longer than 5 minutes (status epilepticus).
- The patient is pregnant, has a history of diabetes, or is injured.
- The seizure has occurred in water, such as a swimming pool or lake.
- There is evidence of head trauma leading to the seizure.
- There is no history of epilepsy or other seizure disorder.
- The seizure is the result of drug or alcohol withdrawal.

Assessment Tips

In about 30 percent of patients who present with status epilepticus, this may be the first seizure and first indication that the patient has a seizure disorder.

Pathophysiology Pearls

Causes of status epilepticus may include hypoxia, stroke, tumors, infections to the brain, electrolyte imbalances (sodium, calcium), cocaine use, hypoglycemia, alcohol and other drug withdrawal, and head injury. Status epilepticus in patients with a known seizure disorder often occurs because the patient did not take his seizure medication or did not take it properly.

Secondary Assessment

In any of the circumstances just listed as transport priorities, begin transport immediately following the primary assessment and conduct the secondary assessment en route to the hospital. Perform a rapid assessment if the patient is postictal and still has an altered mental status, or if he does not have a past medical history of epilepsy or seizures. The head must be assessed for possible signs of injury (Figure 19-4). The pupils may be...
unequal if the brain is injured. Look for medical alert tags that might provide information about the patient.

You may find weakness or paralysis on one side of the body or to one area of the body (hand, arm, or leg) following a seizure. This should disappear as the patient slowly becomes more responsive; however, it may last up to 24 hours. If the weakness does not subside or if paralysis is present upon assessment of the motor and sensory function in the extremities, it may be an indication that a stroke or trauma is the actual cause of the seizure activity. The seizure patient usually regains complete recovery of function soon after the postictal episode. Assess the head and extremities for injury that may have occurred as a result of the muscular activity or the fall to the ground. Some muscle contractions are so severe that a bone injury or dislocation may result. Therefore, inspect and palpate for signs of an injured extremity.

**ASSESSMENT TIPS**

Paralysis to one area or one side of the body may occur following a generalized seizure and may last up to 24 hours. This is referred to as Todd paralysis. It may also indicate that a space-occupying problem in the brain is causing the seizure.

Assess and record the baseline vital signs. The respiration and heart rate may be elevated. The skin is commonly warm and moist.

Apply a pulse oximeter and determine the SpO₂ reading. If the SpO₂ reading is <94%, it may be a result of the inadequate breathing the patient suffered during the active seizure period or, alternatively, it may be an indication of hypoxia that possibly caused the seizure. The low SpO₂ reading may also have resulted from aspiration during the seizure or from fluid leaking out of the capillaries in the lungs and into the spaces between the alveoli and the capillaries from increases in the blood pressure during the seizure.

Since hypoglycemia may trigger a seizure, if protocol permits assess the blood glucose level by using a glucose meter. If the blood glucose is less than 60 mg/dL, you may suspect the seizure is due to a low blood glucose level. Contact medical direction and request an ALS backup if the patient remains unresponsive or if you are unable to administer oral glucose because of the patient’s mental status.
